## ABSTRACT

**Context.** The nature of the close-in rocky planet 55 Cnc e is puzzling, despite it having been observed extensively. Its optical and infrared occultation depths show temporal variability, in addition to a phase curve variability observed in the optical.

**Aims.** We wish to explore the possibility that the variability originates from the planet being in a 3:2 spin-orbit resonance, and thus showing different sides during occultations. We proposed and were awarded Cycle 1 time at the *James Webb* Space Telescope (JWST) to test this hypothesis.

**Methods.** JWST/NIRCam (Near Infrared Camera) observed five occultations (secondary eclipses) of the planet — of which four were observed within a week — simultaneously at 2.1 and 4.5  $\mu\text{m}$ . While the former gives band-integrated photometry, the latter provides a spectrum between 3.9–5.0  $\mu\text{m}$ .

**Results.** We find that the occultation depths in both bandpasses are highly variable and change between a non-detection ( $-5 \pm 6$  ppm and  $7 \pm 9$  ppm) to  $96 \pm 8$  ppm and  $119_{-19}^{+34}$  ppm at 2.1  $\mu\text{m}$  and 4.5  $\mu\text{m}$ , respectively. Interestingly, the variations in both bandpasses are not correlated and do not support the 3:2 spin-orbit resonance explanation. The measured brightness temperature at 4.5  $\mu\text{m}$  varies between 873–2256 K and is lower than the expected day-side temperature of bare rock with no heat redistribution (2500 K), which is indicative of an atmosphere. Our atmospheric retrieval analysis of occultation depth spectra at 4.5  $\mu\text{m}$  finds that different visits statistically favour various atmospheric scenarios including a thin outgassed CO/CO<sub>2</sub> atmosphere and a silicate rock vapour atmosphere. Some visits even support a flat line model.

**Conclusions.** The observed variability could be explained by stochastic outgassing of CO/CO<sub>2</sub>, which is also hinted at by retrievals. Alternatively, the variability observed at both 2.1 and 4.5  $\mu\text{m}$  could be the result of a circumstellar patchy dust torus generated by volcanism on the planet.

## 1. Introduction

Ultra-short-period planets (USPs) provide a unique opportunity to study planets in extreme environments that have no counter-

parts in our Solar System (see Winn et al. 2018, for a review). Many USPs are consistent with a bare rock composition, while some of them might have a secondary metal-rich atmosphere or a disintegrating surface (e.g., Brogi et al. 2012; Kreidberg et al. 2019; Zieba et al. 2022). Being in an orbit around the nearby ( $d = 12.6$  pc), bright naked eye star 55 Cancri ( $V = 5.95$  mag), 55 Cancri e (hereafter 55 Cnc e) is one of the best targets for investigating the nature of a USP. Out of the five known planets in the system, planet e is the only one transiting the star.

\* The photometric and white-light light curves and occultation depth spectra are available in electronic form at the CDS via anonymous ftp to cdsarc.cds.unistra.fr (130.79.128.5) or via <https://cdsarc.cds.unistra.fr/cgi-bin/qcat?J/A+A/>

\*\* e-mail: jayshil.patel@astro.su.se

13      55 Cnc e was discovered by [McArthur et al. \(2004\)](#) with an orbital period of  $\sim 2.8$  d, which was later found to be an alias  
 14      of the true 0.74 d period ([Dawson & Fabrycky 2010](#)). This was confirmed by the detection of planetary transits in the optical  
 15      and infrared (IR) independently ([Winn et al. 2011; Demory et al. 2011](#)), enabling its radius measurement. Together with mass es-  
 16      timates derived from radial velocity measurements, the earlier  
 17      works attempted to constrain the internal structure of the planet and found that the planetary density was consistent with either  
 18      a purely rocky planet, a rocky planet with a thick super-critical  
 19      water envelope, or a carbon-rich interior with no envelope ([De-  
 20      mory et al. 2011; Gillon et al. 2012; Madhusudhan et al. 2012](#)). More recently, [Bourrier et al. \(2018a\)](#) refined the planetary mass  
 21      ( $8.3 M_{\oplus}$ ) and radius ( $1.88 R_{\oplus}$ ) using radial velocity data and HST/STIS (*Hubble Space Telescope / Space Telescope Imaging*  
 22      *Spectrograph*) transit observations. Their internal structure mod-  
 23      elling, based on these updated mass-radius measurements, sug-  
 24      gests a rocky planet surrounded by a heavyweight (high mean  
 25      molecular weight) atmosphere. A low-mean-molecular-weight,  
 26      or lightweight, atmosphere on the planet is not possible because  
 27      of intense radiation from its host star. Atmospheric escape sim-  
 28      ulations also imply that lightweight atmospheres (made of H,  
 29      He) would not survive on 55 Cnc e for a long time period (e.g.,  
 30      [Gillon et al. 2012; Salz et al. 2016; Bourrier et al. 2018a; Zhang et al. 2021](#)). Other attempts to model the internal structure of the  
 31      planet (e.g., [Dorn et al. 2017; Lopez 2017; Crida et al. 2018](#))  
 32      indicate a rocky interior with a gas or water envelope.

40      Soon after its discovery, [Demory et al. \(2012\)](#) used *Spitzer* to detect thermal emission from 55 Cnc e and determined its day-  
 41      side temperature to be around 2300 K. [Demory et al. \(2016a\)](#) constructed a temperature map of the planet using *Spitzer*/IRAC (Infrared Array Camera) phase curve measurements at  $4.5 \mu\text{m}$ . They calculated the average day-side temperature to be around 2350 K with a maximum of  $\sim 2700$  K. Curiously, the hottest location of the planet was found to be shifted by  $\sim 41^\circ$  to the east compared to the sub-stellar point, indicating a strong heat redistribution. On the other hand, the day-night temperature difference was found to be as large as 1300 K, a sign of inefficient heat transport to the night side. These conflicting results led [Demory et al. \(2016a\)](#) to speculate that perhaps efficient heat transport is only happening on the day side of the planet by a thick atmosphere, or alternatively that a molten lava flow is responsible for the heat transport. The inefficiency of energy transport to the night side could be due to gases becoming cold enough to condense. Similarly, a lava stream could be hindered by the surface solidifying at the night side. [Angelo & Hu \(2017\)](#) re-analysed the phase-curve data and confirmed the findings of [Demory et al. \(2016a\)](#). Their physical model of the phase curve allowed them to show that the radiative and advective timescales must be of the same order to reproduce the observed phase curve. This disfavours the lava ocean scenario, since a lava flow would have too large an advective timescale (e.g., [Kite et al. 2016](#)) to be an efficient heat transporter (however interior dynamics models of the planet, in some cases, exhibits a mantle super-plume away from the sub-stellar point, which can potentially interact with the lava ocean and increase its temperature at the location of the plume, mimicking hot-spot offset; [Meier et al. 2023](#)). [Angelo & Hu \(2017\)](#) further propose that a CO or N<sub>2</sub> dominated atmosphere on the day side could explain the phase curve. This claim was corroborated by a 3D global circulation model climate model by [Hammond & Pierrehumbert \(2017\)](#) that could potentially describe the observations, assuming a H<sub>2</sub> + N<sub>2</sub> dominated atmosphere with a trace source of opacity at  $4.5 \mu\text{m}$  (such as CO<sub>2</sub> or H<sub>2</sub>O), coupled with the presence of night-side clouds. A re-

77      cent re-reduction and re-analysis of the *Spitzer* phase curve by  
 78      [Mercier et al. \(2022\)](#) yielded an even larger day-night tempera-  
 79      ture difference with a smaller phase offset, more consistent with  
 80      a poor heat transport typically found on USPs.

81      The heavyweight atmosphere on the planet, which was implied by the *Spitzer* phase curve, climate modelling, and mass-  
 82      radius constraints, is challenging to detect. Numerous observa-  
 83      tions have tried but failed to detect any atmosphere on the planet.  
 84      The singular claim of detection of gas on 55 Cnc e comes from  
 85      [Tsiaras et al. \(2016\)](#), who identified HCN in the atmosphere using HST/WFC3 (Wide Field Camera 3) transit observa-  
 86      tions. However, subsequent observations using high-resolution spec-  
 87      troscopy from the ground could not reproduce the detection of  
 88      HCN ([Deibert et al. 2021](#)). Furthermore, the transit observation  
 89      of 55 Cnc e in the Ly  $\alpha$  band by [Ehrenreich et al. \(2012\)](#) resulted in a non-detection, suggesting the absence of an extended  
 90      H upper atmosphere. This was supported by the non-detection  
 91      of He in the upper atmosphere by [Zhang et al. \(2021\)](#). A lack  
 92      of H and He in the atmosphere could mean that both gases es-  
 93      caped if they were initially accreted from the disc. In addition to  
 94      this, several studies attempted but could not detect other atmo-  
 95      spheric species such as H<sub>2</sub>O, TiO, NH<sub>3</sub>, C<sub>2</sub>H<sub>2</sub>, Fe, Ca, Mg, K,  
 96      Na, and H ([Ridden-Harper et al. 2016; Esteves et al. 2017; Jin-  
 97      dhal et al. 2020; Tabernero et al. 2020; Deibert et al. 2021; Keles  
 98      et al. 2022; Rasmussen et al. 2023](#)). These non-detections mean  
 99      that those species are either absent from the atmosphere or only  
 100      present at very low volume mixing ratios if the mean molecular  
 101      weight of the atmosphere is not too high to be detected by the  
 102      transit observations. Another possibility is that the atmosphere  
 103      of the planet is cloudy ([Mahapatra et al. 2017](#)).

104      The IR observations of 55 Cnc e in emission posed another  
 105      challenge for understanding the behaviour of the planet. [De-  
 106      mory et al. \(2016b\)](#) monitored the occultation depths of 55 Cnc e with *Spitzer* at  $4.5 \mu\text{m}$  during 2012–2013 and found a variable  
 107      occultation depth ranging from 47 ppm to 176 ppm. This translates into a corresponding change in the brightness tempera-  
 108      ture from 1370 K to 2530 K. Variability was also observed in the opti-  
 109      cal bandpass by MOST (Microvariability and Oscillations of STars), which discovered significant changes in phase curves  
 110      over several seasons ([Winn et al. 2011; Dragomir et al. 2014; Sulis et al. 2019](#)). While the optical observations with MOST  
 111      found a significant phase curve amplitude, the secondary occulta-  
 112      tion remained undetected. More recently, CHEOPS (CHaracterising ExOPlanet Satellite) extensively observed 55 Cnc ([Mor-  
 113      rris et al. 2021; Demory et al. 2023; Meier Valdés et al. 2023](#))  
 114      in the optical (G band) and confirmed significant variability not  
 115      only in phase amplitude but also in phase offset and occultation  
 116      depth, where the occultation depths at some epochs were consis-  
 117      tent with zero. TESS (the Transiting Exoplanet Survey Satellite)  
 118      also observed 55 Cnc and found a hint of weak variability in occulta-  
 119      tion depths over three observing sectors ([Meier Valdés et al. 2022](#)). In contrast to the variability of the occultation depths, no  
 120      optical or IR variability has been observed in the transit depths  
 121      (e.g. [Meier Valdés et al. 2023; Bourrier et al. 2018a](#)).

122      Multiple studies in the literature propose various hypothe-  
 123      ses to explain the observed variability of the occultation depth  
 124      of 55 Cnc e in the optical and IR. [Demory et al. \(2016b\)](#) sug-  
 125      gested that plumes from volcanic outgassing on the day side  
 126      could explain the observed variability in emission. Assuming an  
 127      Earth-like composition for the interior, it can release gases such  
 128      as CO or CO<sub>2</sub> that are a significant source of opacity around  
 129       $4.5 \mu\text{m}$ . Gas plumes evolving at different atmospheric pressure  
 130      levels could be inferred as varying temperatures during occula-  
 131      tion observations in the IR. Given that the variability was ob-  
 132      served

served throughout the optical and IR, it was suggested by Morris et al. (2021) that a circumstellar inhomogeneous dusty torus could provide a variable source of opacity. Meier Valdés et al. (2023) studied the dusty torus scenario in detail and concluded that such a torus made up of certain species of a narrow range of particle sizes could indeed reproduce the level of observed variability in the optical. However, a dusty torus should extent out to its Hill sphere and, if opaque, is inconsistent with the observed transit depths (Heng 2023). Heng (2023) argued that a thin, transient outgassed atmosphere is consistent not only with the observed optical and IR occultation depths, but also provides a plausible explanation for their variability. Tian & Heng (2024) demonstrate that CO-CO<sub>2</sub> atmospheres are outgassed under a broad range of conditions (surface pressures, oxygen fugacity, and temperatures).

Since 55 Cnc e is in a very close-in orbit around its host star, Folsom et al. (2020) show that the planet's orbit is inside the stellar Alfvén surface. This means that star-planet interactions (SPIs) are plausible for the system, potentially causing variability-inducing star spots. Bourrier et al. (2018b) proposed coronal rain, a kind of SPI, as a reason for the variability in chromospheric lines that they observed with HST (see also Sulis et al. 2019). Morris et al. (2021) ruled out star spot creation by the planet as a plausible mechanism to explain the optical variability observed by CHEOPS but this does not prohibit other possible forms of SPIs, such as coronal rain.

Although multiple hypotheses have been provided to describe the thermal phase curve and variability from 55 Cnc e, each has difficulties in fully explaining all observed features. The observations with the *James Webb Space Telescope* (JWST) presented here were in part motivated by exploring an alternative hypothesis that the planet rotates at an asynchronous rate to its orbit, potentially explaining both the hot-spot shift into the afternoon and the rapid orbit-to-orbit variability. The idea and the observations motivated by it are presented in Sect. 2, followed by results in Sect. 3. We show the results from atmospheric retrieval analysis in Sect. 3.2. Finally, we interpret the results from our observations and present our conclusions in Sects. 4 and 5, respectively. Details of the data analysis methods used are put into Appendix A.

## 2. Asynchronous rotation scenario for 55 Cnc e observations and methods

### 2.1. 55 Cnc e in a 3:2 spin-orbit resonance

The planet 55 Cnc e orbits its host star in about 17.7 h with a semi-major axis of 0.015 AU (Bourrier et al. 2018a). When a planet is orbiting this close to its host star, it is usually assumed to be in a tidally locked synchronous spin-orbit configuration because of strong tidal forces. However, if the planet is part of a multi-planetary system, gravitational interactions with the other planets can perturb the planet from its synchronous 1:1 spin-orbit configuration. Rodríguez et al. (2012) simulated the tidal evolution of the orbit of 55 Cnc e and showed that there is a reasonable likelihood that the planet is trapped in an asynchronous spin-orbit resonance, with the 3:2 spin-orbit resonance being the most likely after 1:1 synchronous rotation (see also, Callegari & Rodríguez 2013). Asynchronous rotation can thus not be ruled out for 55 Cnc e. The consequence is that the planet would show different faces to the star during the orbit. This in turn means that the hottest point on the planet would not necessarily be the substellar point. Just as on Earth the hottest time of the day is in the afternoon and not at noon, so could thermal inertia on 55 Cnc e

shift its hottest spot to the afternoon (east). The thermal inertia could, like on Earth, be provided by the atmosphere. In the case of a bare rock, thermal inertia could be provided by the heating, melting, and evaporation of the rock in the morning with subsequent condensation and crystallisation in the afternoon. Quantitative models of these scenarios are sensitive to detailed assumptions about the mass and composition of the atmosphere that, in turn, depend on the material equation of state. Using simplified models, Brandeker (2019) showed that the observations up until then could indeed be explained by using reasonable assumptions about the physical properties of the planet, meaning that the asynchronous rotation scenario could not be excluded.

Assuming that the planet is rotating asynchronously in the most probable 3:2 spin-orbit resonance, the planet will show the same face only at every second occultation instead of showing the same face every time. That means the two opposite sides will be seen during consecutive occultations. If there are semi-stable surface features — for example, due to volcanic activity — on different sides of the planet, they will show up differently during alternate occultations. In this case, the observed occultation depths would be expected to highly correlate with the occultation number over a short period, while this correlation could be broken over a longer timescale due to surface changes. The variability in occultation depths observed by Demory et al. (2016b) can then be attributed simply to the planet showing different faces during occultations. Notably, Tamburo et al. (2018), who confirmed the *Spitzer* variability of occultation depths, found the variability to be well fitted by a sinusoidal with a period as short as 2 days, but discarded this solution as being unphysical. However, if the planet is indeed in a 3:2 spin-orbit resonance, it is expected that the period of variability should be equivalent to the synodic period ( $\sim 35.5$  hr), close to the period of 2 days. To further test this intriguing hypothesis of asynchronous rotation and simultaneously sensitively measure potential atmospheric signatures, we designed an observation programme for JWST, which is detailed in the next section.

### 2.2. Observations

If the planet is indeed in a 3:2 spin-orbit resonance, it will show two opposite sides in consecutive occultations. Assuming that the planetary surface evolves slowly, we would then expect every second consecutive occultation to be strongly correlated. Enumerating the occultations by orbit number, we thus requested two 'odd' and two 'even' occultations within a short time-constrained span of two weeks, to rule out significant surface evolution within that time. Since 55 Cnc is a very bright IR target ( $K = 4$  mag), avoiding saturation while observing it with JWST is challenging. From pre-launch estimates, our options were essentially limited to a grism time-series mode of the Near Infrared Camera (NIRCam). The proposal was awarded time in JWST Cycle 1 as GO 2084 (Brandeker et al. 2021). The observation log is provided in Table 1. Due to technical difficulties, only three occultations of the programme were observed within the time constraint of two weeks; the fourth was postponed until five months later. Fortunately, a different programme (GO 1952, Hu et al. 2021) that also targeted 55 Cnc had an occultation observed in the same instrument mode and within the same first week (Hu et al. 2024). In the following, we thus present an analysis of all five visits.

NIRCam offers simultaneous observations in short-wave (SW) and long-wave (LW) channels at  $0.6\text{--}2.3\,\mu\text{m}$  and  $2.4\text{--}5.0\,\mu\text{m}$ , respectively. The SW channel allows the use of a weak lens with a filter providing photometric monitoring of the tar-

get, while the LW channel provides a spectroscopic mode using a grism and a filter. Our observations in the LW channel used the F444W filter with a GRISM element and the RAPID readout mode. On the other hand, the WLP4/F212N2 weak lens/filter with RAPID readout mode was used in the SW channel. Both channels employed the SUBGRISM64 subarray that has 2048 columns and 64 rows. This gave us spectroscopic data between 3.9–5 μm (centred at around 4.5 μm) in the LW channel (or, 4.5 μm channel) and one single photometric data point in a narrow-band (2.3%) bandpass at 2.12 μm from the SW channel (also referred to as the 2.1 μm channel). Given the brightness of the host star, we chose two groups per integration with a total integration time of about 1.03 s.

We used five independent pipelines to reduce and analyse the spectroscopic data at 4.5 μm and two different pipelines to analyse the SW photometric data. The details of these methods are described in Appendix A.

### 2.3. Retrieval model and atmospheric scenarios

We chose two representative independent reductions of occultation depth spectra, from stark and HANSOLO pipelines, to perform atmospheric retrieval. Both reductions differ in their treatment of correlated noise and thus produce slightly different results, which was the reason for choosing two different reductions for retrieval (see Appendix A for more details).

To interpret the observational data, we used the open-source HELIOS-r2 atmospheric retrieval code (Kitzmann et al. 2020), which uses the nested sampling algorithm (Skilling 2004) implemented in the MultiNest library (Feroz & Hobson 2008). For the atmospheric characterisation, we tested four different models with varying levels of complexity. The simplest model tries to fit the observational data with a flat line, while the second one assumes the planet to emit like a pure blackbody of temperature  $T_{\text{bb}}$ . Since observations by, for example, Ehrenreich et al. (2012) and Zhang et al. (2021) rule out the presence of a thick primordial hydrogen-helium atmosphere, a potential atmosphere has to be secondary in nature. There are two essential pathways to create a secondary atmosphere for a hot planet such as 55 Cnc e. The atmosphere can either be dominated by outgassing from the planetary interior (e.g., Tian & Heng 2024) or be created through evaporation of mantle material, or a combination thereof. Thus, for the two atmospheric scenarios, we assumed a secondary atmosphere with outgassed carbon monoxide (CO)/carbon dioxide (CO<sub>2</sub>) (e.g. Heng 2023) or an atmosphere produced by an evaporating mantle with a bulk silicate earth composition that is composed of silicon oxide (SiO), silicon dioxide (SiO<sub>2</sub>), and magnesium oxide (MgO) (Zilinskas et al. 2022).

**Table 2.** Retrieval parameters and prior distributions used for the retrieval models.

Parameter	Type	Prior Value
<i>Flat line</i>		
Occultation depth	uniform	0 ppm – 200 ppm
<i>Blackbody</i>		
$d_{\text{wl}}$	Gaussian	see Table 1
$R_p/R_*$	Gaussian	0.0182 ± 0.0002
$T_{\text{bb}}$	uniform	300 K – 3000 K
<i>Atmosphere</i>		
$d_{\text{wl}}$	Gaussian	see Table 1
$R_p/R_*$	Gaussian	0.0182 ± 0.0002
$p_{\text{surf}}$	log-uniform	10 <sup>-10</sup> bar – 500 bar
$T_{\text{surf}}$	uniform	300 K – 3000 K
$T_{\text{atm}}$	uniform	300 K – 3000 K
$\xi_j$	uniform	10 <sup>-10</sup> ≤ $x_j$ ≤ 1

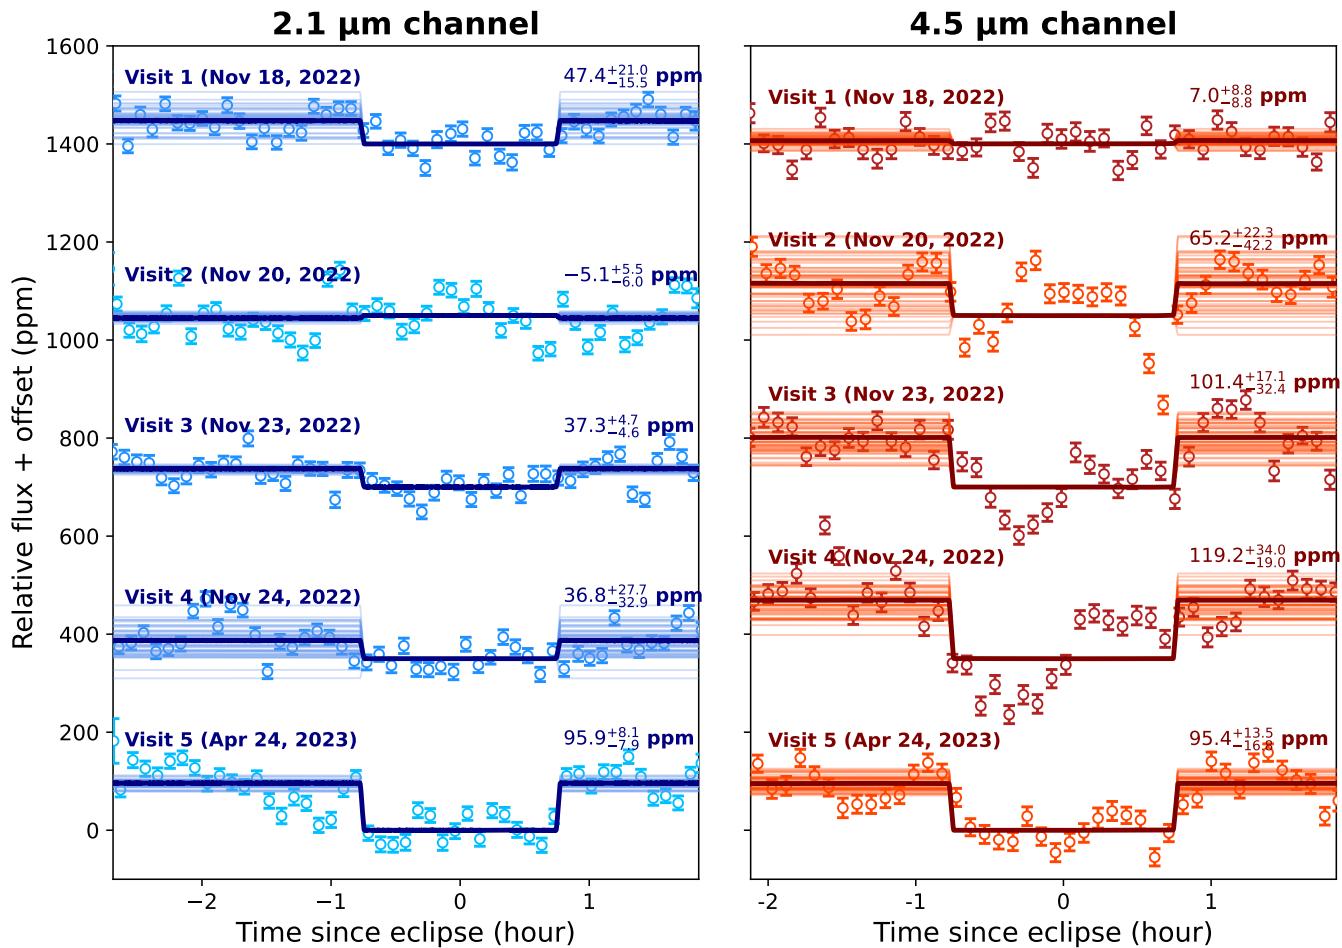

Nested sampling allows Occam's razor (of Ockham 1495) to be enforced via the calculation of the Bayesian evidence (or marginalised likelihood function, see, Trotta 2008, 2017). In practice, this allows us to favour simpler explanations for some of the data (e.g. flat line or blackbody function). To provide good constraints on the Bayesian evidence values, within MultiNest we used 5000 live points (Feroz & Hobson 2008) for each retrieval calculation. Increasing this value further did not alter the resulting evidence values to a significant degree.

The atmosphere was considered to be isothermal with the surface pressure,  $p_{\text{surf}}$ , as a free parameter in the retrieval model. The atmosphere and surface were allowed to have their own distinct temperatures,  $T_{\text{atm}}$  and  $T_{\text{surf}}$ , respectively.

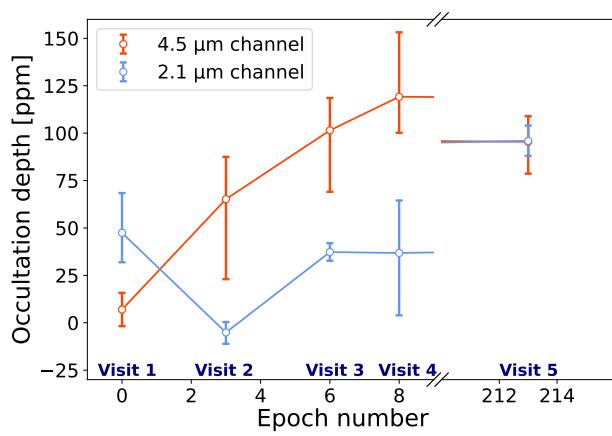

The cross sections of CO, CO<sub>2</sub>, SiO, SiO<sub>2</sub>, and MgO were taken from Li et al. (2015), Yurchenko et al. (2020), Yurchenko et al. (2022), Owens et al. (2020), and Li et al. (2019), respectively. All temperature and pressure-dependent cross sections were calculated with the open-source opacity calculator HELIOS-K (Grimm & Heng 2015; Grimm et al. 2021).

The atmospheric composition in the retrieval model was described through a centred-log-ratio prior that allows a more optimised sampling of the parameter space when the dominant background gas is not known (Benneke & Seager 2012). For a given mixture of  $n$  gases, the centred-log-ratio conversion (clr) for the mixing ration,  $x_j$ , of a given molecule,  $j$ , in the mixture is given by

$$\xi_j = \text{clr}(x_j) = \ln \frac{x_j}{g(\mathbf{x})}, \quad (1)$$

**Fig. 1.** Detrended occultation light curves from the SW photometric channel ( $2.1\mu\text{m}$ , left panel) and white-light light curves from the LW channel ( $4.5\mu\text{m}$ , right panel). Only binned data points are shown here. The darker and lighter shades of the points depict even and odd orbital number parity, respectively. The dates and occultation depth (median and 68-percentile confidence intervals) of the visits are indicated above each plot. The best-fitted models and models computed from randomly selected posteriors to show the model uncertainties are plotted with thick and thin lines.

**Fig. 2.** Observed wide band occultation depths in LW (in orange) and in SW (in blue) channels. The depths are plotted as a function of epoch number starting from the first visit.

336 where  $g(\mathbf{x})$  is the geometric mean of all mixing ratios,  $\mathbf{x}$ :

$$g(\mathbf{x}) = \left( \prod_{j=1}^n x_j \right)^{1/n}. \quad (2)$$

Due to the constraint that

$$\sum_{j=1}^n x_j = 1 \quad \text{or} \quad \sum_{j=1}^n \xi_j = 0, \quad (3)$$

only  $n - 1$  free parameters were needed in the retrieval. We used uniform priors to produce  $\xi_j$  values subject to the constraints that  $\min(\mathbf{x}) = 10^{-10}$  and  $\max(\mathbf{x}) = 1$  (see Benneke & Seager (2012) for details). We note that the prior boundaries for  $\xi_j$  depend on the number of molecules in the retrieval and the chosen value of the smallest allowed mixing ratio.

For the retrieval of the data from the stark reduction, we performed the calculations on the relative occultation depths. Thus, for these calculations, we needed to add an additional free parameter to the retrieval: the white-light occultation depth,  $d_{w1}$ . For these, we used Gaussian priors with the values provided in Table 1. Since HANSOLO reduction provides absolute occultation depths this additional parameter was not needed. Additionally, we binned the data provided by stark which uses the instrument's native resolution to about 30 spectral bins.

All of the retrieval parameters for the different models are summarised in Table 2. The empirically calibrated stellar spectrum of 55 Cnc from Crossfield (2012) was used to trans-

### 3. Results

#### 3.1. Wide-band occultation depths

360 We used six pipelines to reduce and fit our JWST/NIRCam  
361 dataset. The methods are described in detail in Appendix A.  
362 Here, we present results from our primary analysis from the  
363 stark pipeline (Appendix A.1). A summary of our results, along  
364 with the observation log, is tabulated in Table 1.

365 Our main finding is the strong variability in occultation  
366 depths. The white-light occultation depths (computed by fitting  
367 an occultation model to the band-averaged occultation time se-  
368 ries) at 4.5  $\mu\text{m}$  are highly variable even during the short timescale  
369 of a week (Table 1). During the time span of 6 days (8 planetary  
370 orbits), the measured occultation depths at 4.5  $\mu\text{m}$  continuously  
371 increased from basically non-detection in Visit 1 ( $7 \pm 9$  ppm)  
372 to  $119^{+34}_{-19}$  ppm in Visit 4. The occultation depth from our fi-  
373 nal visit (Visit 5), observed 5 months after the other visits, is  
374  $\sim 95 \pm 16$  ppm and consistent with the depths from Visits 3 and  
375 4 but differs significantly from the depths from Visit 1 and 2.  
376 Fig. 2 shows occultation depths as a function of time, illustrating  
377 this point. The best-fitted occultation models along with the  
378 de-trended data are shown in Fig. 1 for all visits.

379 We used an empirically calibrated stellar spectrum of 55 Cnc  
380 from Crossfield (2012), stellar and planetary parameters from  
381 Bourrier et al. (2018a), and the NIRCam response function<sup>1</sup> to  
382 compute brightness temperatures using the measured white-light  
383 occultation depths at 4.5  $\mu\text{m}$ . As is shown in Table 1, the bright-  
384 ness temperature changes significantly from 873 K to 2256 K  
385 within a week. Notably, the brightness temperature almost dou-  
386 bled from Visit 1 to 2; that is, after only three planetary orbits.

387 Similarly, the 2.1  $\mu\text{m}$  channel occultation depths are also  
388 variable. Within a week, the 2.1  $\mu\text{m}$  occultation depths remained  
389 almost constant at around 40 ppm for Visits 1, 3, and 4, while  
390 we found a non-detection of occultation for Visit 2 that was ob-  
391 served between Visit 1 and 3 (see, Fig. 2). However, the final  
392 observation that was taken 5 months later (Visit 5) shows a sig-  
393 nificantly higher occultation depth of  $96 \pm 8$  ppm, which is almost  
394 equal to the depth observed at 4.5  $\mu\text{m}$  in the same epoch. The cor-  
395 responding brightness temperatures varies significantly between  
396 1247 K and 3138 K (see, Table 1). Interestingly, there is no cor-  
397 relation between the occultation depth variability observed at 2.1  
398 and 4.5  $\mu\text{m}$  (Fig. 2). Fig. 1 present the de-trended SW data with  
399 best-fitted models.

The variability, plotted in Fig. 2, is clearly not correlated with  
400 the parity of the orbit number. Occultation depths are also vari-  
401 able between occultations from orbits of the same parity; for in-  
402 stance, in even (Visits 1, 3, and 4) or odd (Visits 2 and 5) visits.  
403 The rapid variability thus cannot be explained by simply alter-  
404 nating between two sides of the planet. This does not rule out  
405 the planet rotating asynchronously but does mean that an expla-  
406 nation for the rapid variability has to be found elsewhere.  
407

All visits showed various degrees of significant correlated  
408 noise of unknown origins, in both the 2.1 and 4.5  $\mu\text{m}$  chan-  
409 nels. The leftover correlated noise can be seen in Fig. 1 and  
410 are also quantified in the Allan deviation plots in Fig. A.3. We  
411 performed an injection-retrieval test to estimate proper uncer-  
412 tainties on occultation depths in the presence of correlated noise  
413 (see, Sec. A.1.1). We report uncertainties from this analysis in  
414 Table 1. We, however, found that various methods to account  
415 for correlated noise could somewhat change the results of occul-  
416 tation depths and emission spectra (see, Appendix A for more  
417 details).  
418

#### 3.2. Occultation depth spectra and atmospheric retrieval

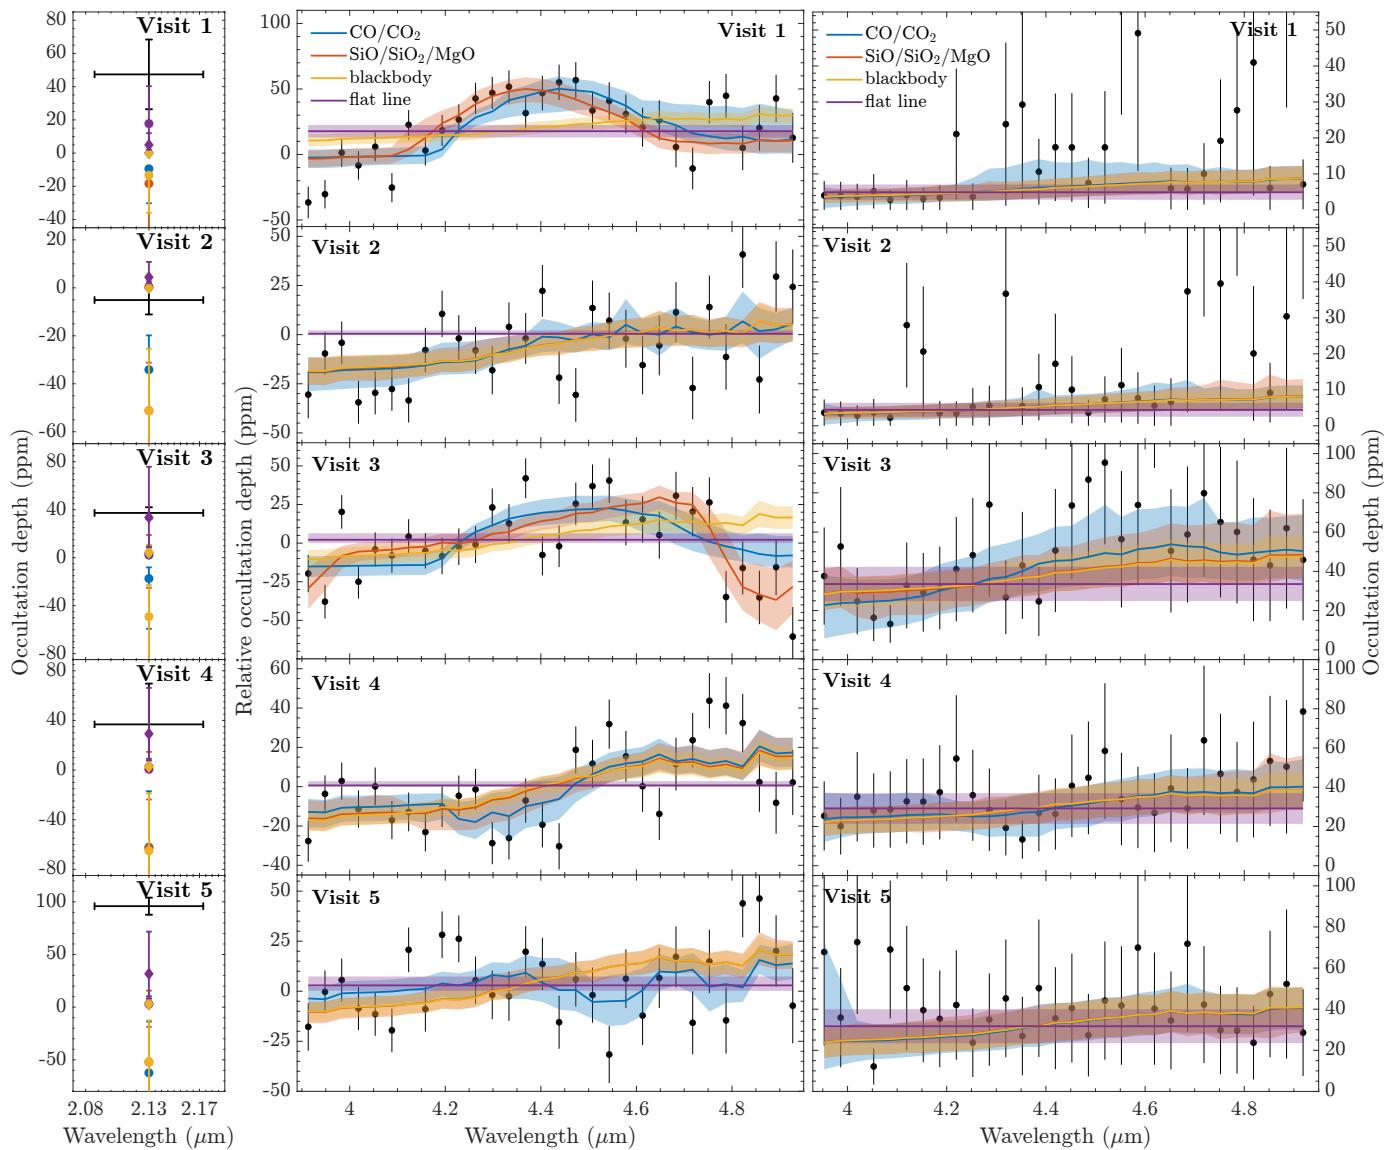

We computed the relative occultation depth spectra, as is out-  
420 lined in Appendix A.1, using the stark reduction, and the abso-  
421 lute occultation depth spectra from the HANSOLO pipeline, as is  
422 described in Appendix A.4. Since different methods of handling  
423 the correlated noise could lead to different results, we chose  
424 to perform atmospheric retrieval analysis on results from two  
425 pipelines, stark and HANSOLO, which use two representative  
426 techniques to deal with the correlated noise (see, Appendix A  
427 for details). The occultation depth spectra, shown in Fig. A.1,  
428 are also variable from visit to visit and do not show any consis-  
429 tent spectral features.  
430

##### 3.2.1. Summary of the retrieval results

The retrieval results for the two different reductions across all  
432 five visits and for the four different model scenarios described in  
433 Sect. 2.3 are summarised in Table 3. The table shows the result-  
434 ing Bayesian evidence values  $\ln \mathcal{Z}$  and the Bayes factors,  $B$ , with  
435 respect to the models with the highest likelihood value. The for-  
436 mer are marked in bold for every visit. Fig. 3 additionally shows  
437 the posterior spectra for all models, visits, and reductions. The  
438 detailed posterior distributions for all atmospheric retrievals can  
439 be found in Figs. 4 and 5, as well as in Appendix C.  
440

The results presented in Table 3 suggest that for the HANSOLO  
441 reduction, the planetary blackbody model is always the preferred  
442

<sup>1</sup> <http://svo2.cab.inta-csic.es/theory/fps/>

**Fig. 3.** Posterior spectra for all model scenarios and visits. The left column shows predicted occultation depths in the shortwave channel. The black data points indicate the observed value, while diamonds represent the retrieval results for the HANSOLO reduction and squares refer to the outcome for the stark. The vertical error bars represent the  $1-\sigma$  confidence intervals. The middle column shows the posterior spectra for stark, while the column on the right-hand side displays the corresponding results for HANSOLO. Solid lines refer to the median spectra from the posterior sample, while the shaded areas correspond to the  $1-\sigma$  intervals. We note that the retrievals for the stark reductions were made for relative occultation depths, i.e. the mean occultation depths in the middle column are close to zero.

model. This is likely caused by the relatively large errors of the reduction that results in the retrieval favouring a simpler model as can clearly be noticed in the spectra shown in the right column of Fig. 3.

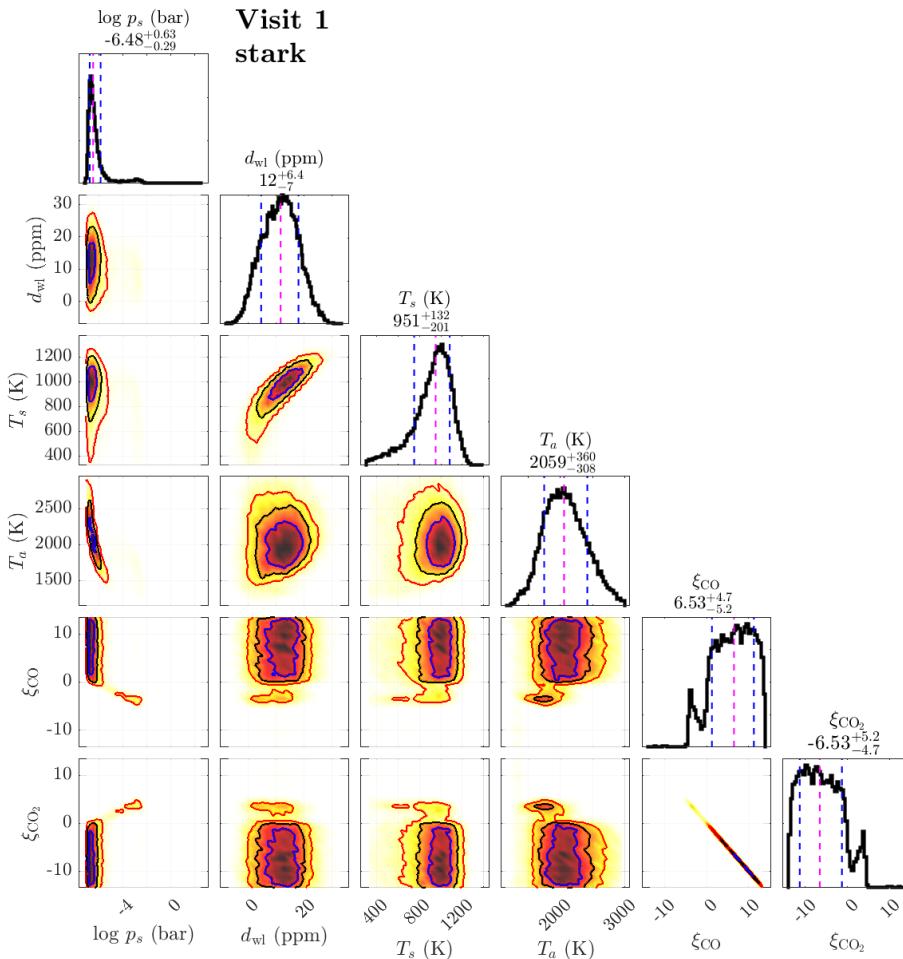

However, for most visits, the preference for the simple black-body model is not statistically significant. The more complex atmospheric scenarios usually have a Bayes factor of less than three, which suggests that they are essentially equally likely. For the first three visits, a flat-line fit to the measured spectrum is effectively ruled out by the Bayesian evidence. The last two visits, on the other hand, can be fit with any of the four models. There seems to be little statistical preference for any of the different modelling scenarios.

The results for the stark reduction show a much broader range of different models that are statistically preferred. As is suggested by Table 3, the first visit strongly prefers a CO/CO<sub>2</sub> atmosphere, and the second visit can be explained by either a

CO/CO<sub>2</sub> atmosphere, a planetary blackbody, or a silicate vapour atmosphere, while the third model overwhelmingly prefers the SiO/SiO<sub>2</sub> scenario. The fourth visit is consistent with a planetary blackbody spectrum, as well as an atmosphere with CO and CO<sub>2</sub>, or SiO, SiO<sub>2</sub>, and MgO. Finally, the last visit strongly prefers a flat-line model.

### 3.2.2. Detailed posterior distributions

Detailed posterior distributions for the preferred model from the stark reduction of Visit 1 (CO and CO<sub>2</sub>) and Visit 3 (SiO, SiO<sub>2</sub>, and MgO), where atmospheric models are favoured, are shown in Figs. 4 and 5. The posterior distributions for the first visit reveal a bimodal distribution for the surface pressure,  $p_{\text{surf}}$ , and the abundances of CO and CO<sub>2</sub>. As the two-dimensional correlation plots suggest, the surface pressure has a solution with a very low value of about  $10^{-6.5}$  bar that is dominated by CO in

**Fig. 4.** Posterior distributions of the free parameters for the first visit, representing the CO/CO<sub>2</sub>-atmosphere scenario. Results are shown for the stark reduction. We note that  $\xi_{\text{CO}_2}$  is not a free parameter in the retrieval but was calculated during a postprocess procedure following the requirement that in each posterior sample the sum of all  $\xi$  values must be zero.

composition, as well as a higher-pressure mode at about  $10^{-3}$  bar that contains mostly CO<sub>2</sub>. For comparison, if the outgassing flux were to be balanced by flux-limited atmospheric escape then the implied surface pressure is  $\sim 10^{-7}$  bar (Heng 2023). At about 2000 K, the atmosphere temperature is much warmer than the retrieved temperature for the surface. It is also important to note that the posterior distribution for the white-light occultation depths,  $d_{\text{wl}}$ , is shifted from its prior value of  $7 \pm 9$  ppm, though they are both still within their  $1-\sigma$  intervals.

The posterior distribution for the SiO/SiO<sub>2</sub>/MgO model shown in Fig. 5 for the third visit, on the other hand, exhibits a unimodal pressure distribution with a median value of about 0.1 bar. Here, the atmosphere is clearly dominated by SiO<sub>2</sub>, with only an upper limit for SiO and essentially no constraints on MgO. The posterior spectra shown in Fig. 3 clearly show the drop-off in the occultation depth near a wavelength of  $4.8 \mu\text{m}$  caused by SiO<sub>2</sub>. Just like in the previous CO/CO<sub>2</sub> scenario for Visit 1, the retrieved atmosphere temperature is again much higher than the one of the surface.

### 3.2.3. Blackbody temperatures

The resulting posterior distributions of the blackbody temperature models are shown in Fig. 6 for all visits and the two different reductions. In the case of the HANSOLO reduction, the blackbody is always the preferred model according to the Bayesian evidence, though, as was previously mentioned, this preference is statistically not very significant.

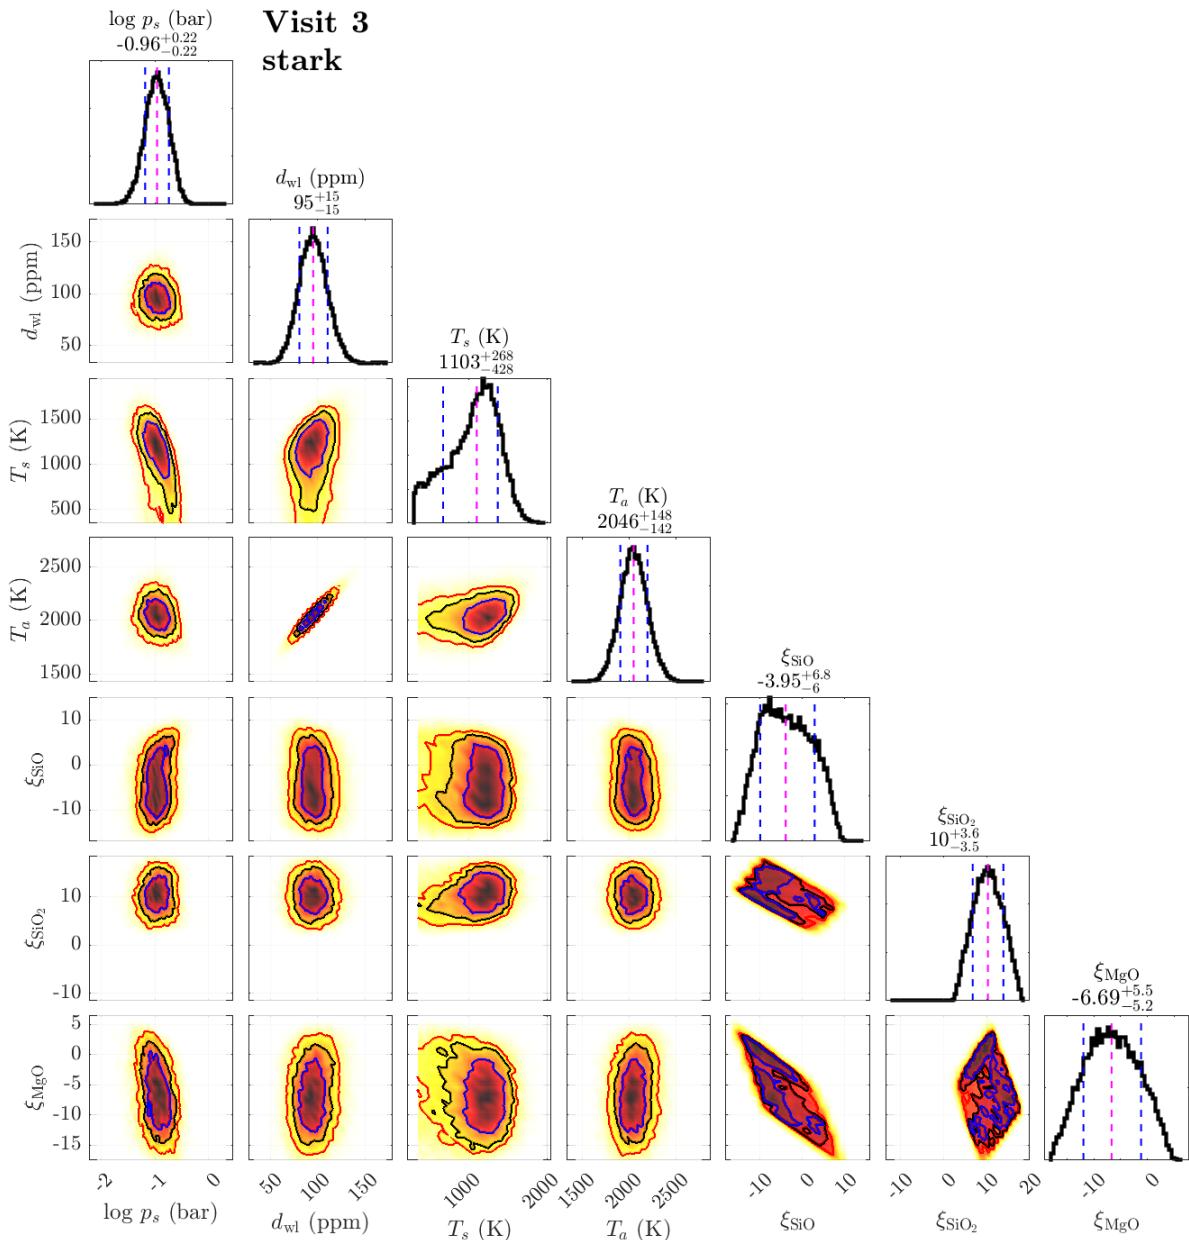

As the distributions depicted in the figure suggest, the temperatures retrieved from the HANSOLO observational data are found in two different clusters. A low-temperature mode near 750 K is found for Visits 1 and 2 and a second one at about 1200 K to 1300 K for the other three visits. The temperatures are quite well constrained with  $1-\sigma$  intervals usually in the range of about  $\pm 100$  K, despite the rather large errors on the observational data points (see Fig. 3).

For stark, the temperatures are clustered much closer together around a mean temperature of 1500 K, in comparison to the HANSOLO reduction; however, these temperatures are less well constrained, with  $1-\sigma$  intervals typically covering a range of several 100 K. This is likely caused by the white-light occultation depths that are directly correlated with these temperatures. Following Table 1, they have in general quite large associated errors that translate into less well-constrained temperatures.

### 3.2.4. Surface pressures

For the two model scenarios that involve atmospheres, we also retrieved the surface pressure. For the CO/CO<sub>2</sub> model, the corresponding posterior distributions are shown in Fig. 7, while those for the SiO/SiO<sub>2</sub>/MgO scenario are shown in Fig. 8.

In general, the HANSOLO reduction only weakly constrains the surface pressure with posteriors that usually cover the entire prior range of the pressure from  $10^{-10}$  bar to 500 bar. The posterior distributions seem to be essentially bimodal for almost every visit, with a very low-pressure mode and a high-pressure one. These more or less unconstrained pressures are the result of the

**Fig. 5.** Posterior distributions of the free parameters for the third visit, representing the SiO/SiO<sub>2</sub>/MgO-atmosphere scenario. Results are shown for the stark reduction. We note that  $\xi_{MgO}$  is not a free parameter in the retrieval but was calculated during a postprocess procedure following the requirement that in each posterior sample, the sum of all  $\xi$  values must be zero.

rather large errors of the observational data from the HANSOLO reduction. Those make it difficult to provide good constraints for actual atmospheric models.

For the stark reduction, the results are more diverse. Some visits seem to result in very well-constrained surface pressures. This includes Visits 1 and 5 for the CO/CO<sub>2</sub> model (see upper panel of Fig. 7) and Visits 1 and 3 for the SiO/SiO<sub>2</sub>/MgO case (see upper panel of Fig. 8).

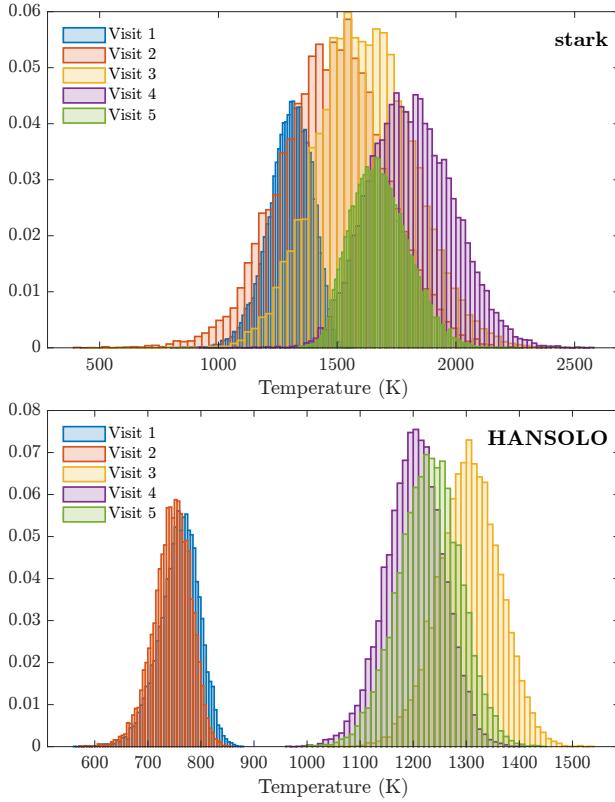

Other visits show the same behaviour as for the HANSOLO reduction: rather unconstrained surface pressures with usually a bimodal posterior distribution. Even though not very visible in Fig. 7, the posterior distribution for Visit 1 is also bimodal in shape, with a smaller, high-pressure mode of an atmosphere dominated by CO<sub>2</sub>, as discussed above.

We note that our retrieved surface pressures differ from the one reported by Hu et al. (2024), which corresponds to our Visit

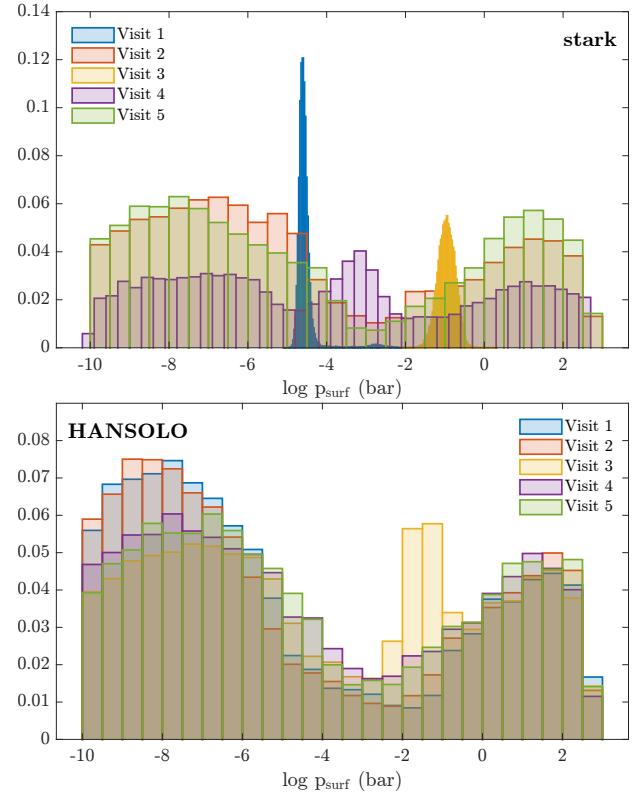

4 and is based on the JWST program by Hu et al. (2021). However, given that even the two reductions of the same data in our study produce different results regarding the atmospheric properties, this is not too surprising. Furthermore, Hu et al. (2024) employed a different retrieval approach. This includes not using the white-light eclipse depths of the NIRCam data, imposing a lower limit on the surface temperature and allowing for a non-radiatively interacting background gas. The latter assumption especially will affect the posterior distributions of the surface pressure.

### 3.2.5. Surface and atmosphere temperatures

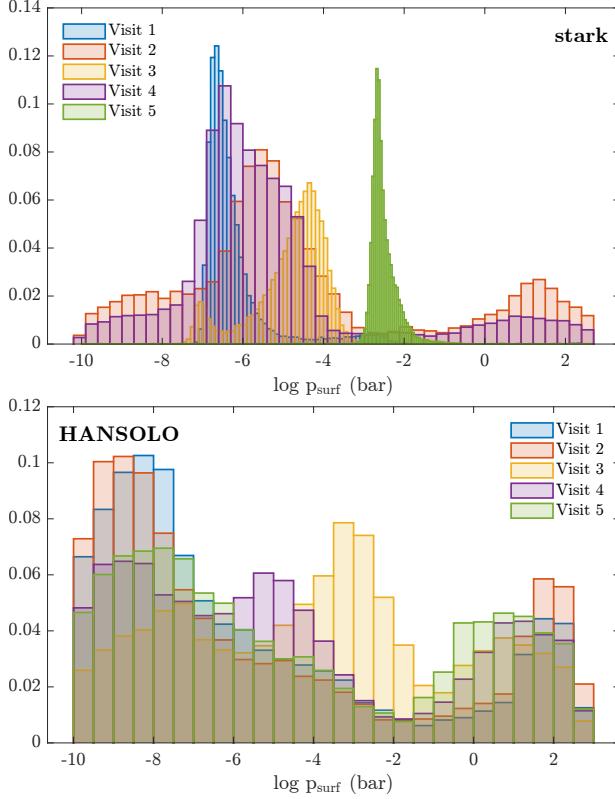

For the CO/CO<sub>2</sub> model, we present the posteriors for the surface and atmosphere temperatures in Fig. 9. As is discussed in Sect. 2.3, we have allowed these two temperatures to have dis-

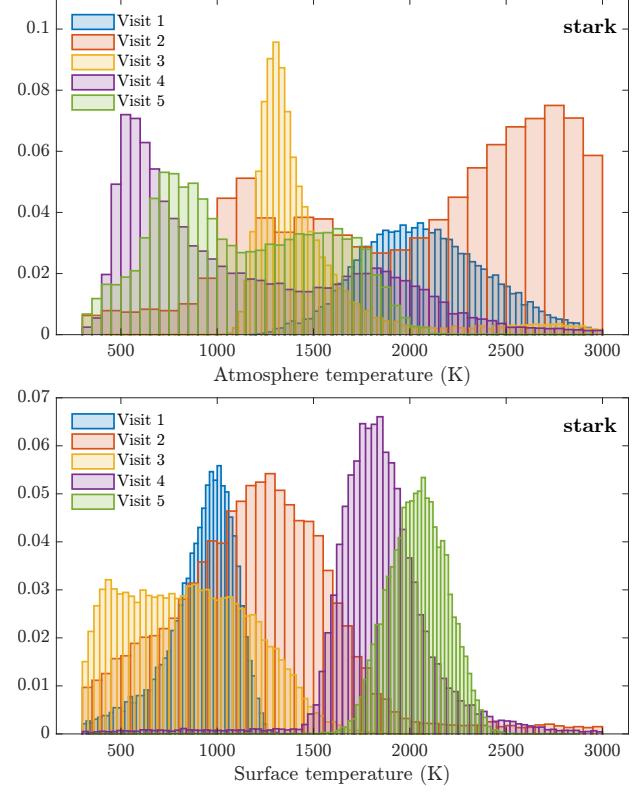

**Fig. 6.** Retrieved temperatures for all five visits using the blackbody model. Top panel: Results for the **stark** reduction. Bottom panel: **HANSOLO**.

**Fig. 8.** Surface pressure posterior distribution from the  $\text{SiO}/\text{SiO}_2/\text{MgO}$  model for all five visits. Top panel: Results for the **stark** reduction. Bottom panel: **HANSOLO**.

**Fig. 7.** Surface pressure posterior distribution from the  $\text{CO}/\text{CO}_2$  model for all five visits. Top panel: Results for the **stark** reduction. Bottom panel: **HANSOLO**.

**Fig. 9.** Posterior distributions for the atmosphere (top) and surface temperatures (bottom). The distributions are shown for the  $\text{CO}/\text{CO}_2$  model and the **stark** reduction.

tinct values. We only present the posteriors for the stark reduction since, as was shown above, the HANSOLO one does not provide good constraints on the atmospheric properties.

Just like the surface pressure, the temperatures are rather well constrained for some visits, such as the surface temperatures for Visits 4 and 5. Observational data from other visits yield much broader distributions, such as Visit 2, some of which also seem to possess a bimodal shape or only provide upper limits.

Visit 1 is the only case where the atmosphere seems to have a distinctly higher temperature than the surface. For other visits, this trend is less clear. For example, Visit 5 yields a very high surface temperature but the atmospheric one is less well constrained and only seems to provide an upper limit that is roughly equal to the surface temperature. In the case of Visit 3, this situation is reversed. Here, the atmosphere temperature is constrained with a median value of roughly 1400 K, while the surface temperature only has an upper limit of about the same value.

#### 4. Interpretation of observations

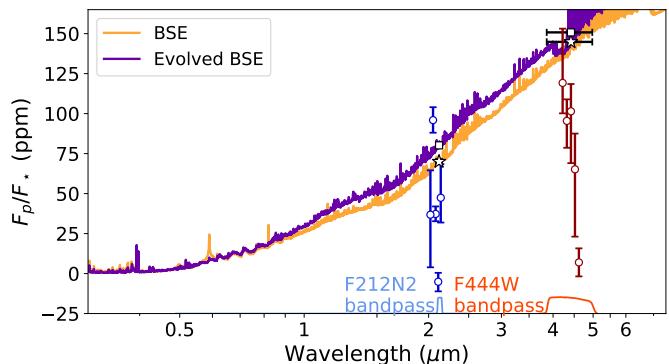

As was mentioned in Sect. 2.1, if the variability in the emission from the planet is caused by the planet showing different faces during consecutive occultations, we would expect the occultation depth to be correlated with the orbit number. However, Fig. 2, which plots the occultation depths as a function of orbit number, shows that this is not the case. This means that the observations give no support for a 3:2 spin-orbit resonance being the root cause for the variability. It is still possible that the planet is trapped in some higher-order spin-orbit resonance, but to show this by establishing a pattern would require many more occultation observations than we currently have.

There are several hypotheses that could potentially explain the full or part of the observations. We outline two such models in the subsections below: a transient outgassing atmosphere model and a circumstellar material supported by the volcanism model. Moreover, the NIRCam data also constrain the presence of spectral features from a mineral atmosphere resulting from a purported lava ocean, as is described in Sect. 4.1 below.

##### 4.1. Constraints on silicate atmosphere on 55 Cnc e

Being in proximity to its host, the substellar temperature on 55 Cnc e can reach > 2000 K. The surface of the planet at such a high temperature is expected to be molten if there is no atmosphere on the planet. A molten surface on the planet could then produce a thin rock vapour atmosphere on the planet. Zilinskas et al. (2022) recently calculated self-consistent models of outgassed atmospheres for all USPs at the time. They solved the radiative transfer equations along with equilibrium chemistry models for the outgassed atmosphere to compute temperature-pressure profile and emission spectra. They showed that gases such as SiO, SiO<sub>2</sub>, Na, and MgO are some of the main constituents of these outgassed atmospheres. Their models for 55 Cnc e<sup>2</sup> are shown in Fig. 10 overplotted with our observations. The models assume bulk silicate (oxidised) Earth (BSE) composition for the planet with unevolved and evolved surface with 80% outgassed efficiency (evolved BSE composition).

All of their models with different outgassing efficiencies predict occultation depths of 70–80 and 145–150 ppm for NIRCam 2.1 and 4.5 μm channels. As is depicted in Fig. 10, these values are larger compared to our observations. Some occultation

**Fig. 10.** Theoretical models of evaporating lava atmospheres for 55 Cnc e from Zilinskas et al. (2022). Two models are for bulk-silicate composition (in yellow) and for evolved bulk-silicate composition (in purple). Also overplotted are photometric occultation depths from 2.1 μm channel (in blue) and white-light occultation depths for 4.5 μm channel (in maroon). The blue and maroon points are slightly spread in wavelength near their bandpasses to avoid overlap. We show the two bandpasses corresponding to both of these channels. The black points show the predicted occultation depths for both NIRCam bandpasses with different shapes representing bulk-silicate (stars) and evolved bulk-silicate (squares) compositions.

depths are, however, consistent with models at 1–3σ. One occultation depth at 2.1 μm in Visit 5 produces a larger depth compared to the models. This hints towards a lack of SW absorbers such as SiO and/or SiO<sub>2</sub> from the atmosphere that are responsible for thermal inversion and, in turn, larger occultation depths in NIRCam bandpasses. Indeed, only one visit (Visit 3) favoured the SiO/SiO<sub>2</sub>/MgO model in the retrieval analysis. The band-averaged occultation depth for this visit at 4.5 μm agrees with the model prediction (145 ppm for BSE case) at 2.4σ. However, the SW occultation depth in this visit is inconsistent with the model prediction at 7σ. We here note that Hu et al. (2024) found that the occultation depths in the MIRI bandpass are significantly lower than what is predicted by Zilinskas et al. (2022) models, and thus do not support the presence of the silicate-rich atmosphere.

At the same time, lower occultation depths in the NIRCam bandpasses could imply the presence of a gaseous species that have opacity sources in our NIRCam bandpasses. Alternatively, the lower occultation depths, translated into lower brightness temperatures, suggest a thick atmosphere with a strong heat redistribution (e.g., Hammond & Pierrehumbert 2017). The estimated day-side brightness temperatures (see, Table 1) at 4.5 μm (Table 1) in all visits are smaller than the expected day-side temperature<sup>3</sup> of 2537 K indicating the presence of heat transfer. In either case, our observations seem to indicate the existence of volatiles in the atmosphere of 55 Cnc e. However, it is still challenging to explain the very large occultation depth (and, thus, hot brightness temperature — 3138 K; see, Table 1) observed at 2.1 μm in Visit 5.

##### 4.2. Constraints on an outgassed secondary atmosphere

Heng (2023) previously suggested that a transient, outgassed secondary atmosphere is capable of simultaneously explaining

<sup>3</sup> Computed using  $T_{\text{day}} = T_{\star} \sqrt{\frac{R_{\star}}{a}} (1 - A_B)^{1/4} f^{1/4}$ , while using zero bond albedo and the heat redistribution factor,  $f = 2/3$ , for a bare rock with no heat redistribution (Burrows 2014; Koll et al. 2019).

<sup>2</sup> All models are publicly available at <https://github.com/zmantas/LavaPlanets>

the observed variability of 55 Cnc e in both the optical/visible and IR range of wavelengths. Specifically, atmospheres of several tens of bars of pure carbon monoxide (CO) are capable of producing occultation depths of about 21 ppm in the CHEOPS and TESS bandpasses, which are consistent with most of the occultation depths measured by CHEOPS (Meier Valdés et al. 2023) and TESS (Meier Valdés et al. 2022). However, a change in atmospheric surface pressure of several tens of bars through loss processes or outgassing over the observed variability timescale in the CHEOPS data is difficult to explain. Such outgassed atmospheres are incapable of producing occultation depths as high as  $\approx 40\text{--}50$  ppm, which were measured thrice in Fig. 3 of Meier Valdés et al. (2023). Similarly, they cannot produce phase variations as high as 110 ppm as measured by MOST (Sulis et al. 2019). It cannot be ruled out that these anomalously high occultation depths are associated with stellar activity.

For the first data reduction (**stark**), the outgassed atmosphere with CO and CO<sub>2</sub> is associated with the highest Bayesian evidence in Visits 1 and 2. Bayesian model comparison does not disfavour this interpretation of Visit 4 as well. Fig. 4 shows the interpretation of the spectrum from Visit 1 using a CO+CO<sub>2</sub> atmosphere. For Visit 3, a silicate-vapour atmosphere is strongly preferred over an outgassed atmosphere (with the logarithm of the Bayes factor being 9.8; Fig. 5). For the more conservative second data reduction (**HANSOLO**), the retrieval associated with the highest Bayesian evidence is a blackbody curve over all 5 visits.

The simplest interpretation of the spectra is using a blackbody curve, which is consistent with the data in Visits 2 and 4 of the **stark** reduction and all five visits of the **HANSOLO** reduction. Fig. 6 shows the posterior distributions of the blackbody temperature. For Visits 2 and 4 of the **stark** reduction, the blackbody temperature is broadly between 1500 K and 2000 K. Note that a blackbody curve does not automatically imply that one is probing a bare rocky surface, since an optically thick, isothermal atmosphere may also produce a blackbody curve (Heng 2023). For the **HANSOLO** reductions, the blackbody temperature is about 750 K for Visits 1 and 2 and increases to about 1250 K for Visits 3, 4, and 5 over a period of about 2.2 days (between Visits 2 and 3). Such a duration is not inconsistent with the radiative timescale, which is under an Earth day for  $\sim 1$  bar atmospheres (Heng 2023). If 55 Cnc e has a bare rocky surface and negligible albedo, then its temperature would be the equilibrium temperature of about 2000 K. If we take these blackbody temperatures (750 K and 1250 K) seriously, then it implies that the observations are not probing a bare rocky surface that has reached a steady state with the stellar instellation, unless one assumes implausibly high surface albedos.

If we focus on the interpretation of the spectra using CO-CO<sub>2</sub> atmospheres, then Figs. 7 and 9 show the posterior distributions of surface pressures, atmospheric temperatures and surface pressures. For the **HANSOLO** data reductions, the surface pressure is unconstrained. For Visits 1, 2 and 4 of the **stark** reduction, the inferred surface pressure is  $\sim 1 \mu\text{bar}$ . The surface temperature is  $\sim 1000$  K, which is only possible if the surface has not come to radiative equilibrium with the stellar instellation because of the presence of an atmosphere. The atmospheric temperature jumps from  $\sim 2000$  K to  $\sim 2500$  K to  $\sim 1500$  K from Visits 1 to 2 to 3. While this is not implausible because of the short radiative timescales, we do not have a mechanism to explain how and why this happens.

### 4.3. Whether a circumstellar inhomogeneous dusty torus can explain variability

Two of our observations, Visit 1 at  $4.5 \mu\text{m}$  and Visit 2 at  $2.1 \mu\text{m}$ , show occultation depths that are consistent with zero at  $1-\sigma$ . These non-detections are challenging to explain with any kind of atmospheric phenomena. Moreover, the occultation depths observed at  $2.1 \mu\text{m}$  and  $4.5 \mu\text{m}$  are not correlated with each other (Fig. 2), which potentially hints towards different origins of variability in different wavelength channels.

A grey absorber could explain the optical and  $2.1 \mu\text{m}$  channel variability. A natural candidate for this grey absorber is a circumstellar dust torus (Sulis et al. 2019; Meier Valdés et al. 2023). The progenitor of the dusty torus could be the volcanism on 55 Cnc e developed by the extreme tidal heating akin to Io (e.g., Oza et al. 2019b; Gebek & Oza 2020). The most common gases from volcanism seen on the Earth, Io, and Venus, such as SO<sub>2</sub>, CO<sub>2</sub>, generate a tenuous atmosphere on the planet. Volcanism, supported by significant tidal heating, is expected to expel a prodigious quantity of dust grains into the upper atmosphere, which ultimately escape the planet's gravitational sphere of influence due to impinging stellar ions. Upon escape, such a mechanism may eventually generate a patchy, circumstellar dust torus, which has been shown to be sufficiently opaque in visible light to produce optical variability (Meier Valdés et al. 2023). Volcanic gases are additional non-trivial sources of opacity in our NIRCam  $4.5 \mu\text{m}$  channel. Analytical models showed that an optically thin (e.g., Gebek & Oza 2020) SO<sub>2</sub> atmosphere with a range of pressures can produce the IR variability observed with Spitzer. Since the Spitzer/IRAC bandpass at  $4.5 \mu\text{m}$  and our NIRCam/F444W bandpass have a large overlap in wavelength, it remains a possibility that a similar thin SO<sub>2</sub> (or any other volcanic gases, such as CO<sub>2</sub>, which also absorbs at  $4.5 \mu\text{m}$ ) atmosphere with several tens of  $\mu\text{bar}$  could explain the observed variability in our NIRCam dataset. To evaluate this idea in detail is however beyond the scope of the present work and instead planned for an upcoming publication (Oza et al., *in prep.*).

The variability at  $2.1 \mu\text{m}$  is difficult to explain with a thin atmosphere consisting volcanic gases such as SO<sub>2</sub> or CO<sub>2</sub> since they do not have significant opacity in the  $2.1 \mu\text{m}$  bandpass. Instead, the dust grains present in the torus could be a cause of this variability, which was also hypothesised by Meier Valdés et al. (2023). If the grain size is larger than  $0.3 \mu\text{m}$  from the size range of  $0.1\text{--}0.7 \mu\text{m}$  discussed in Morris et al. (2021) and Meier Valdés et al. (2023), the particles will be opaque in the  $2.1 \mu\text{m}$  channel, but transparent in the  $4.5 \mu\text{m}$  channel. Although many Earth-like dust species do not survive long enough in the circumstellar environment, dust made of quartz, silicon carbide and graphite can survive a significant fraction of an orbit to generate a patchy torus (Meier Valdés et al. 2023). Following the same formalism from Meier Valdés et al. (2023), the mass loss needed to account for the maximum change in occultation depth (95.9 ppm, in visit 5)  $2.5\text{--}5.7 \times 10^6 \text{ kg s}^{-1}$  is within a factor of two of the maximum escape rate derived by CHEOPS, reported to be as large as  $\sim 2.9 \times 10^6 \text{ kg s}^{-1}$  (Meier Valdés et al. 2023). If the particle size is larger than  $0.7 \mu\text{m}$ , they can, in principle, even explain the variability at  $4.5 \mu\text{m}$  channel. However, the non-correlation of occultation depths at  $2.1 \mu\text{m}$  and  $4.5 \mu\text{m}$  channels suggests that although the two sources may be linked, they are indeed distinct absorbers; for example, grains and gas at  $2.1$  and  $4.5 \mu\text{m}$ , respectively, as was mentioned above. However, the effect of the dust torus on the transit observations is yet to be found observationally. In particular, if the dust escape happens during a transit event, dust could float in the Hill sphere of the planet or

771 form a comet-like tail (e.g., Brogi et al. 2012). Both processes  
 772 should affect the transit light curve in the form of a significantly  
 773 large transit depth and an asymmetric transit shape, respectively,  
 774 unless dust very quickly leaves the vicinity of the planet.

775 It is unknown what escape mechanism is currently operating  
 776 at 55 Cnc e, and therefore more phase curve observations, espe-  
 777 cially at shorter wavelengths where Si in the dust have emis-  
 778 sion lines, are needed to monitor the variability. Multiple phase  
 779 curves would scan the whole circumstellar region over time to  
 780 determine the location of the dusty torus and how it evolves,  
 781 helping in a better understanding of the escape mechanism and  
 782 thus variability. However, based on its close proximity several  
 783 mechanisms including canonical photoevaporation and boil-off  
 784 (Affolter et al. 2023) are able to reproduce the estimated es-  
 785 cape rate. For close-in rocky bodies like 55 Cnc e, more ener-  
 786 getic plasma escape mechanisms including ion-neutral interac-  
 787 tions such as atmospheric sputtering (Oza et al. 2019b; Meyer  
 788 zu Westram et al. 2024), which, similar to Io, drive a feedback  
 789 process sourced by the melting and degassing of the rocky body  
 790 itself via induction-heating (Lanza 2021) and two body tidal-  
 791 heating (Oza et al. 2019a; Quick et al. 2020; Charnoz et al.  
 792 2021).

793 The aforementioned escape mechanisms are source-limited  
 794 by geological activity and expected to vary on orbital timescales  
 795 in phase-curve observations (Meyer zu Westram et al. 2024).  
 796 Source-limited implies that the escape rate is ultimately limited  
 797 by the outgassing rate below the escape layer, such that if the  
 798 supply rate were zero, escape would not occur. Effectively, the  
 799 discussed energetic escape mechanisms naturally generate ex-  
 800 tended neutral and grain clouds that provide a toroidal opacity  
 801 source in the circumstellar environment.

#### 802 4.4. Whether stellar activity can cause the occultation depth 803 variability

804 Stellar activity can, in principle, cause the occultation depth vari-  
 805 ability of 55 Cnc e. Demory et al. (2023) checked whether stellar  
 806 granulation could explain the optical occultation depth variabil-  
 807 ity found with CHEOPS. They, however, rejected stellar activity  
 808 as a source of variability due to very low occultation depths in  
 809 some visits and their detection of a sinusoidal temporal trend of  
 810 the variability. Furthermore, the photometric monitoring of the  
 811 star for about 11 years in the optical from the ground revealed  
 812 a photometric variability of 0.006 mag which is too small to ex-  
 813 plain the ~50 ppm occultation depth variability observed with  
 814 CHEOPS (Fischer et al. 2008; Demory et al. 2023). The stel-  
 815 lar activity signal is expected to decrease at longer wavelengths.  
 816 This means that it is challenging to explain IR variability with the  
 817 photometric variation of mmag level observed by Fischer et al.  
 818 (2008) in the optical. Moreover, the activity has to happen every  
 819 instance during the short time window around the occultation,  
 820 which is improbable. In any case, the inflation of uncertainties  
 821 with the injection-retrieval method accounts for any noise, in-  
 822 cluding the correlated noise. The fact that the maximum differ-  
 823 ence in the occultation depths is significant even with inflated  
 824 uncertainties suggests that the origin of the occultation depth  
 825 variability is not related to the star.

## 826 5. Conclusions

827 We obtained time on JWST/NIRCam to study the day-side  
 828 emission variability of 55 Cnc e (GO 2084: PI Brandeker and  
 829 GO 1952: PI Hu). In particular, we test the hypothesis that  
 830 55 Cnc e is in a 3:2 spin-orbit resonance, thus showing different

831 faces at every occultation and thereby explaining the observed  
 832 day-side variability and also the hot-spot displacement from the  
 833 sub-stellar location. The prediction was that this would result in  
 834 occultation depths highly correlated with their orbital number  
 835 parity, at least over short timescales.

836 We observed five occultations of 55 Cnc e in two wavelength  
 837 bands, or channels, a spectroscopic band at  $4.5\mu\text{m}$  and a single  
 838 photometric band at  $2.1\mu\text{m}$ . Four of them are observed within a  
 839 week, that is, in the duration of eight planetary orbits, while the  
 840 last was observed after five months. We analysed the data using  
 841 six different pipelines. Our main finding is that the occultation  
 842 depths change strongly, from a non-detection to 100 ppm, and  
 843 rapidly (within a week). The variability is however not observed  
 844 to correlate with the occultation number parity, implying that a  
 845 planet 3:2 spin-orbit resonance is not the reason for its variabil-  
 846 ity. The variability is observed in both  $2.1$  and  $4.5\mu\text{m}$  channels,  
 847 but is curiously not correlated between channels. The estimated  
 848 brightness temperature at  $4.5\mu\text{m}$  varies between 873 K – 2256 K.  
 849 These values are less than the predicted day-side temperature in  
 850 case of zero heat redistribution and zero albedo, 2537 K, which  
 851 hints at the presence of a planetary atmosphere enabling the heat  
 852 redistribution.

853 The spectroscopic data at  $4.5\mu\text{m}$  is affected by correlated  
 854 noise of unknown origin. Although the results from different  
 855 reductions overall agree well with each other, there are sev-  
 856 eral differences in white-light occultation depths and emission  
 857 spectra that can be attributed to different treatments of corre-  
 858 lated noise. We select two representative reductions, stark and  
 859 HANSOLO, to perform atmospheric retrieval. Our atmospheric  
 860 retrieval was performed using two simple atmospheric models  
 861 containing an isothermal atmosphere made up of either CO/CO<sub>2</sub>  
 862 or SiO/SiO<sub>2</sub>/MgO. Additionally, we also tested a blackbody  
 863 model and a flat line model with no atmospheric features. Re-  
 864 trievals performed with HANSOLO results mainly favour a black-  
 865 body model owing to larger error bars on the occultation depths.  
 866 However, other models with CO/CO<sub>2</sub> or SiO/SiO<sub>2</sub>/MgO were  
 867 not discarded either, statistically. The retrievals with stark pre-  
 868 fer CO/CO<sub>2</sub> atmospheres in at least two visits, SiO/SiO<sub>2</sub>/MgO  
 869 atmosphere in one visit and blackbody and flat line models in  
 870 the remaining two visits. The CO/CO<sub>2</sub> atmosphere could be gen-  
 871 erated from outgassing of the surface (e.g., Heng 2023). The  
 872 outgassing could be stochastic and thus can potentially explain  
 873 the variability. As already advocated by Heng (2023), simultane-  
 874 ous observations in the optical and IR are needed to corroborate  
 875 (or refute) the presence of a transient outgassed CO/CO<sub>2</sub> atmo-  
 876 sphere.

877 The occultation depth variability in the  $2.1\mu\text{m}$  channel, es-  
 878 pecially its uncorrelated behaviour with its  $4.5\mu\text{m}$  channel counter-  
 879 part, is challenging to explain with a simple atmospheric model.  
 880 It is possible that the variability seen at  $2.1\mu\text{m}$  and that at  $4.5\mu\text{m}$   
 881 have different origins. A circumstellar inhomogeneous cloud of  
 882 dust could potentially describe the variability at  $2.1\mu\text{m}$ . Vol-  
 883 canism induced by extreme tidal heating of 55 Cnc e could be  
 884 a natural source of dust in the atmosphere of the planet which  
 885 would eventually escape the planet and generate a patchy dusty  
 886 torus in the circumstellar environment. The presence of dust in  
 887 the circumstellar environment could also be helpful in the inter-  
 888 pretation of several non-detection of occultation depths found in  
 889 our observations as it could hide our view of the planet. More  
 890 observations at shorter wavelengths, for example, in ultraviolet,  
 891 would help to more strongly constrain the presence of a circum-  
 892 stellar patchy dust torus. Simultaneous observations in near and  
 893 mid-IR around 4 and  $8\mu\text{m}$  where volcanic gases CO<sub>2</sub>/SO<sub>2</sub> have  
 894 opacity would be helpful in constraining their presence. Such

895 multiple observations in the optical and IR would not only constrain the presence of a circumstellar dust torus and atmosphere  
896 on the planet but also probe how these components evolve with  
897 time, essentially distinguishing both scenarios discussed in this  
898 work.

900 While we do find a hint of an atmosphere on the planet in at least some visits, corroborating [Hu et al. \(2024\)](#), the simple picture of a static atmosphere cannot explain all observational features. A more complex model, including an outgassed atmosphere, circumstellar material, and perhaps dynamical processes in the atmosphere, would probably be needed to explain the entire range of observations. Moreover, given the strong variability of the system, simultaneous multi-wavelength observations would go a long way to distinguish between possible explanations and help probe the true nature of 55 Cnc e.

910 **Acknowledgements.** We would like to thank an anonymous referee for their detailed referee report and suggestions which significantly improved the manuscript. JAP acknowledges Néstor Espinoza for discussing the peculiarities of JWST data analysis. JAP would like to thank Ludmila Carone for an insightful dialogue about theoretical models of the planet. ## 1083 Appendix A: Data analysis methods

1084 This section details six independent methods of analysing the  
 1085 JWST/NIRCam data. In Table A.1, we summarise the white-  
 1086 light occultation depths between about 4 and 5  $\mu\text{m}$  (see, below  
 1087 for exact wavelength range for different methods) and photomet-  
 1088 ric occultation depths at 2.1  $\mu\text{m}$ . Figure A.1 compares the rela-  
 1089 tive occultation depth spectra for all visits from different meth-  
 1090 ods. It can be seen from Fig. A.1 and Table A.1 that the re-  
 1091 sults obtained with various independent analysis methods over-  
 1092 all agree with each other, however, there are some differences  
 1093 which could be attributed to the different handling of correlated  
 1094 noise in the data. For example, HANSOLO reduction uses Gaus-  
 1095 sian processes (GP) to model the correlated noise and thus pro-  
 1096 duces results, white-light and spectroscopic occultation depths,  
 1097 that are the most distinct from the rest of the methods. On the  
 1098 other hand, reduction methods from, for example, stark, inflate  
 1099 error bars on occultation depths to account for correlated noise.  
 1100 We use results from HANSOLO and stark as two representative  
 1101 methods in our atmospheric retrieval analysis and interpretation.  
 1102 We describe each analysis method below.

### 1103 A.1. stark

1104 As described in Sect. 2.2, the observations were carried out us-  
 1105 ing NIRCam grism timeseries observing mode, which has two  
 1106 channels, an LW spectroscopic channel (at 4.5  $\mu\text{m}$ ) and an SW  
 1107 photometric channel (at 2.1  $\mu\text{m}$ ). We analysed both datasets with  
 1108 our pipeline.

#### 1109 A.1.1. Long-wave data analysis

1110 We downloaded uncalibrated data files (uncal files) from the  
 1111 MAST archive and used the official jwst pipeline to produce  
 1112 calibrated files from them. We ran Stage 1 of the jwst pipeline  
 1113 on the uncal files with some modifications. The main change  
 1114 in Stage 1 is that we skipped the dark current step and jump  
 1115 step. This is justified because the dark current level in NIRCam  
 1116 detectors is low. Furthermore, since our observations were car-  
 1117 ried out using only two groups per integration, the jump step  
 1118 would become obsolete. Once we have rateints data from  
 1119 Stage 1 processing, we replace all NaN values in data and er-  
 1120 ror arrays with average values of their neighbouring pixels. We  
 1121 add these pixels to the default bad-pixel map generated by the  
 1122 jwst pipeline. We performed a column-by-column and row-by-  
 1123 row background subtraction to reduce  $1/f$  noise from the data. In  
 1124 this process, we subtracted a median of background pixels from  
 1125 each row while we fitted a line to the column background pix-  
 1126 els and subtracted the estimated background from each column  
 1127 pixel. We then searched for cosmic ray events in the data file  
 1128 by comparing each frame with a median frame. We replaced all  
 1129 detected events with the mean of neighbouring pixels. However,  
 1130 we added these events to the bad-pixel map in the end. We did  
 1131 not run Stage 2 of the jwst pipeline because it does not change  
 1132 the science images.

1133 Once we have corrected timeseries data, we used an open-  
 1134 source package stark<sup>4</sup> to extract spectra. stark fits one and  
 1135 two-dimensional splines to the spectral data to find a robust es-  
 1136 timate of PSF (point spread function) which can later be used  
 1137 to extract the spectrum. Before spectral extraction, we computed  
 1138 the location of the spectral trace using the centre-of-flux method.  
 1139 We found that the location of the trace on the detector remains

extremely stable and varies only within 0.03 pixels. To estimate the stellar spectrum, we first need to compute the stellar PSF, which we did by fitting splines to the data. As a first approximation, we assume that the PSF does not change with wavelength and with time, so we fitted a 1D spline to the data as a function of distance from trace (known as pixel coordinates). This is a poor assumption because while the PSF stays constant in time, it varies significantly with wavelength. We improved our PSF estimate by fitting a 2D spline to the data as a function of pixel coordinates and wavelength. This robust PSF is then used to find stellar timeseries spectra. We used aperture half-widths of 9 and 2 pixels to fit PSF and extract spectra, respectively. We ran this procedure iteratively. At the end of each iteration, we subtracted the median static residual noise from the raw data. The median static noise is defined as a median difference between data and synthetic images constructed using stellar PSF and spectra. Only two iterations were sufficient to find robust stellar spectra. We compute the white-light light curve by taking a weighted average of light curves in all spectroscopic channels between 3.8612 and 4.9771  $\mu\text{m}$ . The raw white-light light curves for all visits are shown in Fig. A.2.

Now that we have generated light curves we can fit an occultation model to the data. The light curves show a strong ramp in the beginning of each visit (see Fig. A.2), so we discarded the first 35 min of the data before the analysis. In the light curve analysis, we fixed all planetary parameters except occultation depth to their values from the literature (Bourrier et al. 2018a; Meier Valdés et al. 2022). We used a wide uniform prior between -500 to 500 ppm to the occultation depth parameter. We analysed white-light light curves from all five visits together. We used juliet (Espinoza et al. 2019) to fit an occultation model to the data, which uses an occultation model from batman (Kreidberg 2015) and samples posteriors using dynesty (Speagle 2020). In addition to the planetary model, we added linear and quadratic polynomials in time to correct for long-term trends seen in the light curve. The best-fitted values of white-light occultation depths are tabulated in Table A.1. We could not, however, model hour-long correlated noise (see, e.g., Fig. 1), with this simple polynomial model. This is also evident from the Allan deviation plots, shown in Fig. A.3, of residuals that show additional noise at larger bin sizes. The presence of uncorrected correlated noise means that the uncertainties found on the occultation depths are underestimated. We could not determine the origin of this noise: we searched engineering data but could not find any parameter that correlates with the noise, pointing towards a possible astrophysical origin. However, recent transit observations of a bright star (GJ 341, K = 5.6 mag, Kirk et al. 2024) with the same observing mode also show a similar noise as our dataset (see, their Fig. 2). So, the correlated noise could be a previously unknown systematics of the instrument. We looked at the 2D spectral data at the group level to further test this possibility. Generally, the data from the first and last groups are discarded as they could be unreliable. We cannot do this since our dataset has only two groups. We took the 2D spectral data for both groups independently and extracted spectral timeseries from them in exactly the same manner described earlier. We finally computed and analysed white-light light curves from both groups. We found that the correlated noise similar to the integration level light curve is also present at ‘group level’ white-light light curves. This suggests that the correlated noise does not originate from unreliable first and last groups (see also our companion paper for more details, Patel & Brandeker, *in prep*).

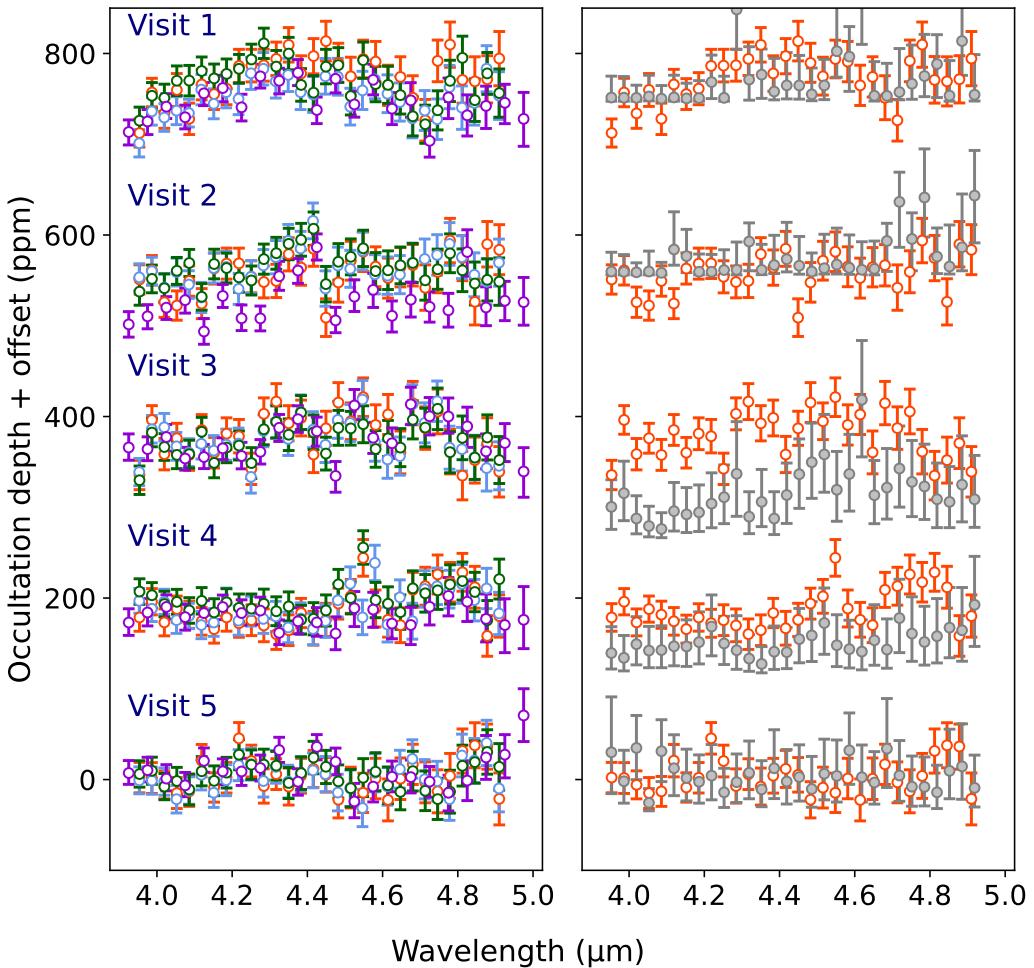

We perform injection-retrieval tests on the white-light light curves to estimate proper uncertainties on the occultation depths

**Notes.** The uncertainties are 68 percentile of the corresponding posterior distribution. Visit 4 is the archival observation from [Hu et al. \(2024\)](#).

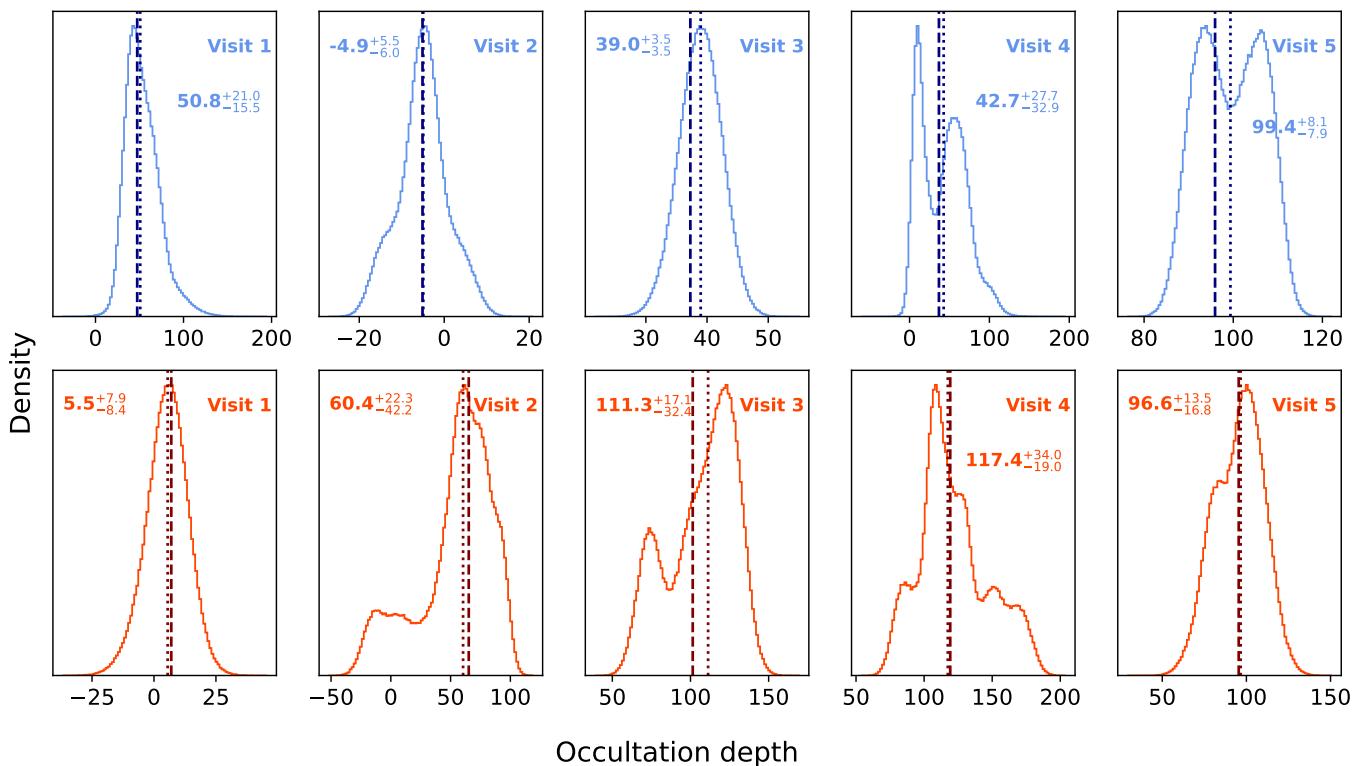

**Fig. A.1.** Comparison of occultation depth spectra for all observations from different methods: (*Left*) Relative occultation depth spectra from stark (baseline spectra, in orange), Eureka! (in blue) and transitspectroscopy (in green), and absolute occultation depth spectra minus white-light depth for SPARTA (in purple). (*Right*) stark relative occultation depth spectra (in orange) and HANSOLO absolute occultation depth spectra minus white-light depth (in grey).

**Fig. A.2.** Raw photometric light curves from the SW channel at  $2.1 \mu\text{m}$  (in blue) and raw white-light light curves from the LW channel at  $4.5 \mu\text{m}$  (in orange) for Visit 1 to 3 and 5 (GO 2084, in the top panel) and for Visit 4 (GO 1952, bottom panel). A darker and lighter shade of colours depicts the even and odd parity of the observations. The darker points on the top of the main data show the binned data points.

**Fig. A.3.** Allan deviation plots of residuals from photometric light curve analysis from  $2.1\text{ }\mu\text{m}$  (SW) channel (left panel, in blue) and  $4.5\text{ }\mu\text{m}$  (LW) channel white-light light curve analysis (right panel, in orange).

**Fig. A.4.** Posteriors of occultation depths from injection-retrieval exercise (see, text) for  $2.1\text{ }\mu\text{m}$  (SW) channel (the top row, in blue) and  $4.5\text{ }\mu\text{m}$  (LW) channel (the bottom row, in orange). The dashed and dotted vertical lines are injected and retrieved – a median of the posteriors – values of occultation depths, respectively. The median and 68-percentile confidence intervals of the posterior are written on the top of the plots.

in the presence of correlated noise. We first subtract the normalised planetary signal from the raw white-light light curve keeping the long-term trend and the correlated noise as it is in the data. We next produced 1000 realisations of light curves by injecting an occultation signal at random times in the data. The depth of the signal is equal to the median value from the full light curve analysis presented earlier. In this process, we made sure that the full signal remained inside the data. We fit a full model, consisting of an occultation model and polynomial – linear and quadratic – trend, using `juliet` to each of the realisations. We build a posterior of occultation depth using randomly selected samples from the posteriors of occultation depth in each realisa-

tion. These posteriors, shown in Fig. A.4 for all visits, are clearly not Gaussian for most of the cases illustrating the effect of correlated noise. A 68-percentile confidence interval of this posterior should be more representative of uncertainties on white-light occultation depths. In the cases where the uncertainties obtained this way were smaller than the ‘white’ uncertainties from the light curve analysis, we choose to report the larger value.

The correlated noise is also present in the spectroscopic light curves of each column. We first boosted the estimated errors of the spectroscopic light curves and the white-light light curve according to the scatter in the light curves. Then we divided spectroscopic light curves from each column with the white-light light curve to remove the correlated noise from the spectroscopic data. This mostly removed correlated noise from the spectroscopic light curves. Finally, we computed relative occultation depths as  $1 - (F_{\text{in}}/F_{\text{out}})$ , where  $F_{\text{in}}$  and  $F_{\text{out}}$  are the flux inside and outside of the occultation duration, respectively. Before computing this, we made sure that the baseline before and after the occultation signal was the same. Note that we compute relative occultation depths at the native resolution of the instrument before binning them to a lower resolution. This method minimises the impact of any leftover 1/f noise in the data (see, e.g., Espinoza et al. 2023).

### 1239 A.1.2. Short-wave data analysis

1240 The Stage 1 processing of  $2.1\mu\text{m}$  channel uncal files was  
 1241 mostly done in the same way as for the  $4.5\mu\text{m}$  channel uncal  
 1242 files described above. The main difference is that here we only  
 1243 perform a row-by-row background subtraction. The SW PSF  
 1244 spreads to almost all pixel ranges along the column so that there  
 1245 are very few background pixels along the column making it im-  
 1246 possible to perform background subtraction along columns.

1247 Once we got rateints data, we performed simple aperture  
 1248 photometry to  $2.1\mu\text{m}$  channel data to obtain a photometric light  
 1249 curve. Before doing this, we computed the centroids of the PSF  
 1250 using the centre-of-flux method. We then computed a growth  
 1251 function – flux inside an aperture as a function of increasing  
 1252 aperture radius – to optimally select an aperture radius. We find  
 1253 that the growth function flattens out at around 45 pixel radius that  
 1254 we eventually used in our analysis. We adapted the photutils<sup>5</sup>  
 1255 (Bradley et al. 2023) package to compute aperture photometry.  
 1256 photutils simply calculates the total flux inside the aperture.  
 1257 Since we already did a row-by-row background subtraction we  
 1258 did not perform another sky annulus subtraction. Uncorrected  
 1259 SW photometric light curves are plotted in Fig. A.2.

1260 We fitted an occultation model to thus-obtained SW light  
 1261 curves in almost the same manner as for the occultation model  
 1262 fitting of LW white-light light curves. The instrumental model  
 1263 used here was different from what was used in the LW case. Here  
 1264 we used a linear polynomial in time and PSF centroids as decor-  
 1265 relation vectors. Additionally, light curves from two of our visits  
 1266 (Visits 1 and 4) show abrupt flux jumps analogous to what was  
 1267 found in Schlawin et al. (2023) (see, Fig. A.2). These flux jumps  
 1268 may or may not be caused by mirror tilting events as described in  
 1269 Schlawin et al. (2023) — a thorough investigation of the origin  
 1270 of these jumps is ongoing (see also our companion work Patel &  
 1271 Brandeker, in prep.). Here we model these flux jumps using mul-  
 1272 tiple step functions; since the jumps are abrupt and affect only a  
 1273 few integrations, it is fairly easy to set the boundaries of step  
 1274 functions. For certainty, we masked all integrations near jumps,

1275 which is safe because the masked integrations consist of only a  
 1276 few per cent of the total number of data points and none of these  
 1277 are near the ingress or egress. Another source of noise in the SW  
 1278 light curves is the high-frequency periodic noise possibly caused  
 1279 by the thermal cycling of heaters in the Integrated Science In-  
 1280 strument Module on JWST (see, Espinoza et al. 2023). This is  
 1281 clearly visible in the power spectrum of the light curve as a peak  
 1282 period near 3.8 min in all visits. We performed a principal com-  
 1283 ponent analysis (PCA) of the PSF time series to see if we could  
 1284 capture this noise as a principal component (PC) or not. Indeed,  
 1285 one of the first PCs in all visits show a periodic pattern with a  
 1286 period of about 3.8 min. While we are uncertain about the origin  
 1287 of this noise, we simply use this PC as a decorrelation vector in  
 1288 our light curve analysis.

1289 In summary, our total model fitted to the SW light curve in-  
 1290 cludes an occultation model, linear models in time, PSF cen-  
 1291 troids and a PC. Step functions were also included as decorre-  
 1292 lation vectors in Visits 1 and 4. We used juliet to fit the light  
 1293 curve data. The best-fitted occultation depths can be found in Ta-  
 1294 ble A.1. These data are also affected by a correlated noise that  
 1295 we could not model using our simple model. This is also evident  
 1296 from the Allan deviation of the residuals shown in Fig. A.3. We  
 1297 performed injection-retrieval tests similar to the LW data analy-  
 1298 sis described in Appendix A.1.1 to properly estimate the uncer-  
 1299 tainties on the occultation depths.

## 1300 A.2. Eureka! — Reduction 1

1301 Here we provide an independent reduction of the SW observa-  
 1302 tions of NIRCam. To reduce the nrca1 uncal files we used  
 1303 Eureka! (version 0.11.dev276+g4e12d23d, Bell et al. 2022)  
 1304 pipeline. Stage 1 consists of running default jwst detector pro-  
 1305 cessing steps, but we skip the saturation step. On stage 2 we only  
 1306 correct for the flat field. On Stage 3, we crop the full array to a  
 1307 window between pixels 1400 and 2000 in the x-axis and between  
 1308 pixels 1 and 64 in the y-axis. We also mask pixels flagged as bad  
 1309 quality and reject outliers above  $7\sigma$  along time axis. We inter-  
 1310 polate bad pixels with a linear function and perform row-by-row  
 1311 background subtraction and 1/f noise correction. Aperture pho-  
 1312 tomety is performed using a circular 40 pixel radius aperture.  
 1313 We subtract the background region with an annulus with an in-  
 1314 ner edge of 45 pixels and an outer edge of 60 pixels. Finally,  
 1315 Stage 4 uses the calibrated files to produce the light-curve. Visit  
 1316 1 and 4 exhibit strong discontinuities, dividing the light-curve  
 1317 into five and six clearly defined segments, respectively. To cor-  
 1318 rect the discontinuities, first, we mask the occultation. To flat-  
 1319 ten the light-curve, we fit a linear function to each segment and  
 1320 then fit an occultation model with exoplanet in a Hamiltonian  
 1321 Monte Carlo algorithm with PyMC3. The rest of the visits did  
 1322 not exhibit such discontinuities and thus we fit only one linear  
 1323 function in time. The resulting occultation depths are shown in  
 1324 Table A.1. Compared to the stark reduction and analysis, all  
 1325 occultation depths are consistent within  $1\sigma$ .

## 1326 A.3. Eureka! — Reduction 2

1327 We produced an independent reduction of the NIRCam spec-  
 1328 tra using the jwst (version 1.12.5, Bushouse et al. 2023) and  
 1329 Eureka! (version 0.9, Bell et al. 2022) pipelines, including  
 1330 purpose-built steps that we describe here. Starting from the un-  
 1331 calibrated raw data, we ran the default jwst detector processing  
 1332 steps up to (and including) the dark current step. Prior to the  
 1333 ramp fitting step, we subtracted from each row the median of

<sup>5</sup> <https://photutils.readthedocs.io/en/stable/index.html>

the left-most 650 pixels in the corresponding row and group. By using these unilluminated pixels as a reference of the level of noise added during readout, this helps reduce 1/f noise. We then applied the remaining `jwst` calibration steps.

We ran the resulting calibrated files through Eureka!. We extracted columns 850 through 1945 and discarded the reference pixels. To straighten the trace, we vertically slid each detector column by an integer number of pixels. We performed background subtraction using the average value of each column, rejecting  $7\sigma$  outliers and excluding a window with a half-width of 15 pixels centred on the trace. Constructing the spatial profile from the median frame, we performed optimal extraction on a region centred on the source and with a half-width of 5 pixels. We generated 30 spectroscopic light curves between 3.9365 and  $4.9265 \mu\text{m}$ , each spanning  $0.033 \mu\text{m}$ . In each light curve, we discarded values farther than  $4\sigma$  from the mean of a sliding window.

The flux in the light curves follows a downward trend with time, and they show significant time-correlated noise. After trimming the initial 20 min of data, where the ramp is the steepest, we modelled the white light curve in each visit as the product of an exponential ramp, a linear polynomial and a batman occultation model, where the occultation depth acted as a free parameter. The fits included an estimated error multiplier to match the scatter in the residuals. We assumed a circular orbit, and fixed the orbital period and mid-transit time to the values in Zhang et al. (2021), and planet radius, orbital inclination and scaled semi-major axis to those reported by Bourrier et al. (2018a). For each visit, we also calculated the relative occultation depths following the methodology outlined in Appendix A.1.1.

#### 1364 A.4. HANSOLO

1365 The HANSOLO (atmospheric transmission Spectroscopy analysis code) pipeline was originally developed to analyse ground-based transmission spectra observed with 8m-class telescopes, but has been adapted to also enable its use on NIRCam data (Lendl et al. 2016, 2017; Ahrer et al. 2023). HANSOLO takes calibrated rateints outputs of the `jwst` pipeline Stage 1 as input.

1371 We used the LACOSMIC algorithm (van Dokkum 2001) to remove cosmic ray effects from the two-dimensional images and identified the spectral trace by using a Moffat function fit to each 1372 column. The sky background was calculated on a column-by-column basis by calculating a linear trend in the column background, which was defined as at least 20 pixels away from the 1373 centre of the spectral trace. This linear trend was then subtracted 1374 from the whole column. We extracted the spectrum by summing 1375 over an aperture with a half-width of 4 pixels.

1376 Consistent with the other reductions, we generated a white 1377 light curve and 30 spectroscopic light curves from which we 1378 clipped the first 35 min to remove the worst of the ramp that is 1379 present in all the data. For each light curve we applied a  $5\sigma$  outlier 1380 rejection filter. We used the light curve and RV fitting code 1381 CONAN to fit the white light curves with an occultation model and 1382 a GP (Gaussian process) with a 3/2 Matern kernel to account for 1383 both the remaining ramp and the correlated red noise. We leave 1384 the occultation depth and the GP parameters (amplitude, length-scale 1385 and a white noise factor) as free parameters and fix all orbital 1386 parameters to the literature values found by Bourrier et al. 1387 (2018a). The white light occultation depths are presented in Table 1388 A.1. We then calculate the common mode for each visit by 1389 removing the fitted occultation from the white light curve and 1390 divide the common mode out of the spectroscopic light curves. 1391 Since the spectroscopic light curves still show some correlated 1392

1393 noise even with the common mode removed, we then fit each 1394 spectroscopic light curve individually in the same way as the 1395 white light curves, with the orbital parameters held fixed and the 1396 occultation depth and GP parameters as free parameters. The re- 1397 sulting emission spectra are shown in Fig. A.1. 1398

#### 1401 A.5. transitspectroscopy

1402 We take the corrected timeseries data from stark LW analy- 1403 sis and use an open-source tool `transitspectroscopy` (Es- 1404 pinoza 2022)<sup>6</sup> for spectral extraction. We first use a centre of 1405 flux method to find the location of trace on the detector. We used 1406 the optimal extraction algorithm from Marsh (1989) to extract 1407 1D stellar spectra from the timeseries data. In this procedure, 1408 we used an aperture half-width of 3 pixels. The optimal extrac- 1409 tion naturally clips all outliers not identified by the pipeline. We 1410 masked all such  $10\sigma$  outliers. White-light light curves for each 1411 visit were computed by taking a weighted average of spectro- 1412 scopic light curves between  $3.8612$  and  $4.9771 \mu\text{m}$ . 1413

1414 We used `juliet` to fit the occultation model to the white- 1415 light light curve data. In addition to the occultation model 1416 (from batman, Kreidberg 2015), our full model includes linear, 1417 quadratic and cubic polynomials to model a long-term decreasing 1418 trend. We also added white noise to the errors on the flux. 1419 We fixed all planetary parameters except occultation depth from 1420 the literature (Bourrier et al. 2018a; Meier Valdés et al. 2022). 1421 The median and 68-percentile confidence intervals for the best- 1422 fitted occultation depths are tabulated in Table A.1. We also de- 1423 termined relative occultation depth spectra using the procedure 1424 described in Appendix A.1.1 and plotted in Fig. A.1. 1425

#### 1426 A.6. SPARTA

1427 Our SPARTA reduction is very similar to that used in Hu 1428 et al. (2024), which analysed the one occultation observed by 1429 GO 1952 (PI Hu). The steps that we used to go from the un- 1430 calibrated files to the spectroscopic light curves are identical. In 1431 stage 1, we perform superbias subtraction, reference pixel sub- 1432 tractation, non-linearity correction, dark subtraction, and up-the- 1433 ramp fitting (which amounted to subtracting the two reads since 1434 we only have two). In stage 2, we remove the background, which 1435 also removes some of the 1/f noise because we perform row-by- 1436 row subtraction in addition to column-by-column subtraction. In 1437 stage 3, we perform sum extraction with a window half-width of 1438 2 pixels, obtaining spectroscopic light curves. 1439

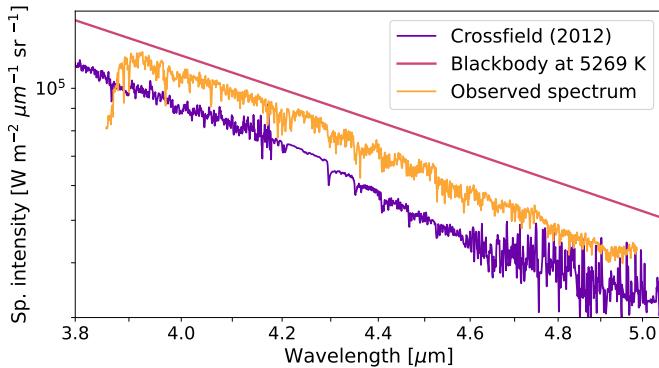

1440 Using emcee, we fit the white light curve with a model that 1441 has the occultation time and occultation depth as astrophysical 1442 free parameters, while the light curve normalisation factor, expo- 1443 nential ramp amplitude and timescale, x and y linear correlation 1444 parameters, linear slope with time, and error inflation multiple 1445 are free systematics parameters. We save the systematics model 1446 corresponding to the best fit to the white light curve. To fit the 1447 spectroscopic light curves, we first divide each light curve by the 1448 aforementioned systematics model, and then fit the result with 1449 a model that includes every parameter in the white light curve 1450 fit except the occultation time (which we fix to the white light 1451 value). 1452

## 1449 Appendix B: Properties of the star

### 1450 B.1. Observed stellar spectrum

1451 We produced rateints files from uncalibrated data using the  
1452 jwst pipeline using the same procedure as described in Ap-  
1453 pendix A.1.1. We then ran Stage 2 of the jwst pipeline with  
1454 some modifications, namely skipping the flat fielding and  
1455 extract1d steps, to produce calibrated spectrum files. This was  
1456 followed by correcting data and error files for NaN and cosmic  
1457 rays as described in Appendix A.1.1. Despite being classified  
1458 as a point source by the jwst pipeline, the physical unit of  
1459 calibrated 2D spectrum data is given as MJy/sr. We converted  
1460 the units to Jy using the pixel area quoted in a header file of  
1461 calints data products from Stage 2 of the jwst pipeline. We  
1462 finally extracted the spectrum using stark as described in Ap-  
1463 pendix A.1.1. We extracted a timeseries of spectra from part of  
1464 the data from our most recent visit, Visit 5. A median spectrum  
1465 of these timeseries spectra is plotted in Fig. B.1 and compared  
1466 with the Crossfield (2012) empirical spectrum and black body  
1467 spectrum. We found that similar to Hu et al. (2024), the NIR-  
1468 Cam observed spectrum is discrepant with the Crossfield (2012)  
1469 empirical spectrum. We think that this may be because of im-  
1470 proper photometric correction for bright stars provided by the  
1471 jwst pipeline. Furthermore, Hu et al. (2024) found that their  
1472 MIRI observed spectrum agrees very well with Crossfield (2012)  
1473 spectrum. Here, we use the Crossfield (2012) spectrum in our at-  
1474 mospheric retrieval analysis.

### 1475 B.2. Stellar parameters from modelling

1476 We modelled 85 publically available spectra from the High Ac-  
1477 curacy Radial velocity Planet Searcher (HARPS; Mayor et al.  
1478 2003) spectrograph with a resolution of 115 000. The spectra  
1479 were co-added and modelled with Spectroscopy Made Easy<sup>7</sup>

<sup>7</sup> <http://www.stsci.edu/~valenti/sme.html>

(SME; Valenti & Piskunov 1996; Piskunov & Valenti 2017) version 5.2.2 and the stellar atmosphere grid Atlas12 (Kurucz 2013). SME computes synthetic spectra and adjusts the chosen free parameters based on comparison with the observed spectrum. We modelled one parameter at a time, utilising spectral features sensitive to different photospheric parameters and iterating until all parameters converged. Throughout the modelling, we held the macro- and micro-turbulent velocities,  $V_{\text{mac}}$  and  $V_{\text{mic}}$ , fixed at 2.7 km s $^{-1}$  (Doyle et al. 2014) and 0.95 km s $^{-1}$  (Bruntt et al. 2008). A description of the modelling procedure is detailed in Persson et al. (2018). The results are listed in Table A.6.

The stellar radius was modelled with the SED fitting software astroARIADNE<sup>8</sup> (Vines & Jenkins 2022) using priors from SME and photometry from the Johnson  $B$  and  $V$  magnitudes (APASS),  $GG_{\text{BP}}G_{\text{RP}}$  (DR3),  $JHK_S$  magnitudes (2MASS), WISE W1-W2, and the Gaia DR3 parallax. We utilised three different atmospheric model grids from Phoenix v2 (Husser et al. 2013), Castelli & Kurucz (2004), and Kurucz (1993). The final radius was computed with Bayesian Model Averaging and was found to be  $0.953 \pm 0.011 R_{\odot}$ . The luminosity is  $0.63 \pm 0.02 L_{\odot}$ , and the visual extinction is consistent with zero ( $0.03 \pm 0.03$ ). We derived a stellar mass of  $0.639^{+0.021}_{-0.020} M_{\odot}$  interpolating the MIST (Choi et al. 2016) isochrones with astroARIADNE. Our results are very close to previous results; von Braun et al. (2011) derive a stellar radius of  $0.943 \pm 0.010 R_{\odot}$  based on interferometric measurements and the parallax from van Leeuwen (2007). Updating this calculation with the Gaia DR3 parallax, this radius becomes  $0.962 \pm 0.010 R_{\odot}$  in good agreement with our results.

## 1509 Appendix C: Detailed retrieval posterior 1510 distributions

In this appendix we present all posterior distributions from 1511 our retrieval calculations for the CO/CO<sub>2</sub> and SiO/SiO<sub>2</sub>/MgO 1512 cases. The posterior distributions are shown for the stark and 1513 HANSOL0 reductions. Due to the fact that for the HANSOL0 reduc- 1514 tion, the retrievals are performed on absolute occultation depths, 1515 the posterior distributions do not include the white-light occulta- 1516 tion depths parameter  $d_{\text{wl}}$ .

It is also important to note that the depicted centre-log-ratio 1517 posterior  $\xi_j$  for the last molecule is not a free parameter in the re- 1518 trieval, as was mentioned in Sect. 2.3. Instead, we calculated the 1519 corresponding posterior distribution following the requirement 1520 that for each posterior sample, the sum of all  $\xi$  values must be 1521 zero.

For Visits 1 and 3, the posterior distributions are already 1522 shown in Figs. 4 and 5 in the main text and are not repeated 1523 here. The corresponding posterior spectra for the posteriors are 1524 shown in Fig. 3. All plots containing posterior distributions can 1525 be found on Zenodo<sup>9</sup>.

<sup>8</sup> <https://github.com/jvines/astroARIADNE>
